PREFACE

The following "Introductory View of the Principles of Manufactures" is an attempt to render very few words necessary in this place in the form of preface; and those who will have reference rather to the arrangement of the articles than to an illustration of the general principles of the undertaking. Although a subject so extensive as that which is here attempted to be described is not easily condensed into one volume, yet it is hoped that very few of our important branches of British Manufacture have been omitted, and of the Machinery and actually employed in Manufactures all that appeared to be most interesting has been selected.

The arrangement which has been adopted will, it is also hoped, be found satisfactory. In the more substantial parts of the general articles had alone been regarded, we should in many cases have had the application of principles described before the principles themselves had been illustrated, which would have been a more convenient and all the advantages derivable from it would have been lost. It would have been attended with too great a liability to any particular article. The want of any comprehensive knowledge supplied by the author, and the necessity of having the author at liberty to place the articles in their natural order of dependence on each other.

The first section treats of the different forces employed to give motion to Machinery, as a human strength, the power of horses, wind, water, and steam; secondly, of the forces which retard the motion, as friction, rigidity, resistance, &c.

The elementary parts of mill-work and their construction are then described, with different methods of conveying and discharging Machinery—modes of equalizing the motion, and converting motion from one species to another; the theory of the fly-wheel, &c.

The principles of mill-work being thus separately illustrated, we next describe the construction of mills, but simply with reference to the power which puts them in motion, without regard to the work they are intended to perform; that and the nature of the work is then divided into hand-mills, tread-mills, horse and water-mills, wind-mills, and steam-mills. The steam-engine, according to the state of the subject, becomes also a mill of a like class, but from its importance it is made to form the subject of a distinct section. Here we examine first the elastic power, and other properties of steam, and finally the nature of the several contrivances for the production of steam.

P R E F A C E.

THE following "Introductory View of the Principles of Manufactures" is so explicit as to render very few words necessary in this place in the form of preface; and these few will have reference rather to the arrangement of the articles than to an illustration of the general principles of the undertaking. Although a subject so extensive as that which is here attempted to be described is not easily condensed into one volume, yet it is hoped that very few, if any, important branches of British Manufacture have been omitted; and of the Machinery not actually employed in Manufactures all that appeared to be most interesting has been noticed.

The arrangement which has been adopted will, it is also hoped, be found satisfactory. If the mere alphabetical order of the several articles had alone been regarded, we should in many cases have had the application of principles described before the principles themselves had been illustrated, which must have been found inconvenient, and all the advantages derivable from it would have been, the means it would have afforded of turning readily to any particular article. The want of this convenience is, however, supplied by the addition of an extensive alphabetical index, which, while furnishing to the reader a ready means of reference, has left the author at liberty to place the articles in their natural order of dependence on each other.

The first Section treats of the different forces employed to give motion to Machinery, *i. e.* human strength, the power of horses, wind, water, and steam; secondly, of the forces which retard its action, *i. e.* friction, rigidity, resistance, &c.

The elementary parts of mill-work and their construction are then described, with different methods of engaging and disengaging Machinery,—modes of equalizing, transmitting and converting motion from one species to another, the theory of the fly-wheel, crank, &c.

The principles of mill-work being thus separately illustrated, we next describe the form and construction of mills, but simply with reference to the power which puts them in motion, without regard to the work they are intended to perform; they are thus naturally divided into hand-mills, tread-mills, horse and cattle mills, wind and water mills. The steam-engine, according to this view of the subject, becomes also a machine of a like class, but, from its importance, it is made to form the subject of a distinct Section. Here we examine, first, the elastic power and other properties of steam; secondly, the claims of the several candidates for the honour of discovering its application

INTRODUCTORY VIEW OF THE PRINCIPLES OF MANUFACTURES. By CHARLES BABBAGE, Esq., F.R.S., &c.	1
MANUFACTURES. By PETER BARLOW, Esq., F.R.S., &c.	85

PREFACE

The following "Introductory View of the Principles of Manufactures" is an attempt to render very few words necessary in this place in the form of preface, and which will have reference rather to the arrangement of the articles than to an illustration of the general principles of the undertaking. Although a subject so extensive as that which has been attempted to be described is not easily condensed into one volume, yet it is hoped that very few, if any, important branches of British Manufacture have been omitted, and of the *Machinery* and *Manufactures* all that appeared to be most interesting and useful.

The arrangement which has been adopted, will, it is also hoped, be found satisfactory. If the more philosophical parts of the general articles had alone been presented, or if, in many cases, there had been the application of principles described before the principles themselves had been illustrated, which would have been found inconvenient, and all the advantages derivable from it would have been lost. It would have been a waste of labour, turning readily to any particular article. The want of the *Machinery* and *Manufactures* articles, by the addition of an extensive appendix, has been supplied by the author at liberty to place the articles in their natural order of dependence on each other.

The first section treats of the different forces employed to give motion to Machinery, as human strength, the power of horses, wind, water, and steam; secondly, of the forces which retard its action, as friction, rigidity, resistance, &c.

The elementary parts of mill-work and their combination are then described, with different methods of conveying and discharging Machinery—modes of equipping frames, and converting motion from one species to another, the theory of the fly-wheel, cranks, &c.

The principles of mill-work being thus separately illustrated, we next describe the form and construction of mills, but simply with reference to the power, which puts them in motion, without regard to the work they are intended to perform. They are then naturally divided into hand-mills, tread-mills, horse and water-mills, wind-mills, and steam-mills. The steam-engine, according to the extent of the subject, becomes also a mill. The steam-engine, however, is a new subject, and is treated in a separate section. It is to be examined first, the steam power, and other properties of steam, and then the nature of the various machines in the power of steam, and the nature of the various machines in the power of steam.

P R E F A C E.

THE following "Introductory View of the Principles of Manufactures" is so explicit as to render very few words necessary in this place in the form of preface; and these few will have reference rather to the arrangement of the articles than to an illustration of the general principles of the undertaking. Although a subject so extensive as that which is here attempted to be described is not easily condensed into one volume, yet it is hoped that very few, if any, important branches of British Manufacture have been omitted; and of the Machinery not actually employed in Manufactures all that appeared to be most interesting has been noticed.

The arrangement which has been adopted will, it is also hoped, be found satisfactory. If the mere alphabetical order of the several articles had alone been regarded, we should in many cases have had the application of principles described before the principles themselves had been illustrated, which must have been found inconvenient, and all the advantages derivable from it would have been, the means it would have afforded of turning readily to any particular article. The want of this convenience is, however, supplied by the addition of an extensive alphabetical index, which, while furnishing to the reader a ready means of reference, has left the author at liberty to place the articles in their natural order of dependence on each other.

The first Section treats of the different forces employed to give motion to Machinery, *i. e.* human strength, the power of horses, wind, water, and steam; secondly, of the forces which retard its action, *i. e.* friction, rigidity, resistance, &c.

The elementary parts of mill-work and their construction are then described, with different methods of engaging and disengaging Machinery,—modes of equalizing, transmitting and converting motion from one species to another, the theory of the fly-wheel, crank, &c.

The principles of mill-work being thus separately illustrated, we next describe the form and construction of mills, but simply with reference to the power which puts them in motion, without regard to the work they are intended to perform; they are thus naturally divided into hand-mills, tread-mills, horse and cattle mills, wind and water mills. The steam-engine, according to this view of the subject, becomes also a machine of a like class, but, from its importance, it is made to form the subject of a distinct Section. Here we examine, first, the elastic power and other properties of steam; secondly, the claims of the several candidates for the honour of discovering its application

to mechanical purposes, that is, of the invention of the steam-engine. Next is described the several parts of the modern steam-engine under its different forms, and their combination in the single and double-acting engine, high-pressure engine, vibrating engine, &c.; and, lastly, their comparative effect, and the method of estimating their power.

In the following Section is illustrated the application of steam power to Mining, to Navigation, to locomotive engines on railways and common roads. In the course of these articles is shown the method of working copper-mines, tin-mines, iron-mines, coal-mines, &c., with the product of each kind in Great Britain for several successive years. The extraordinary progress of steam navigation also is exhibited, and the probable extent and great mercantile advantages likely to be derived from the establishment of railways.

The next division treats of such machines as admit of description without an immediate reference to the mechanical processes they are intended to effect; and these, conforming rather to general use than to any intrinsic difference, are divided into engines and machines, and the former into different classes, as cutting engines, hydraulic engines, fire-engines, &c.; but the machines being of various kinds, not easily separated into classes, are treated of under one head, and are arranged alphabetically.

Having thus illustrated the elementary principles of practical mechanics, and shown the combination of the several parts in the production of different engines and machines, we pass to their application to various purposes. In a preceding chapter is described the construction of mills, with reference only to the agent by which they were put in motion; and in this place we treat of their application to different processes without reference to their first moving power, as, for example, bark-mills, cement-mills, colour-mills, corn-mills, oil-mills, saw-mills, sugar-mills, snuff and tobacco mills, &c., which concludes our First Part or division. The Second Part treats of mechanical processes and manufactures. A classification is here again attempted by first describing those mechanical establishments generally spoken of under the term Works, as iron-works, copper-works, and others for the production of metals; works for the production of acids, salts, pigments, &c., employed in Manufactures and for domestic purposes; works for forming artificial substances, as bricks, porcelain, glass, &c.; gunpowder-works, sugar-works, and those for bleaching, dyeing, calico-printing, and for tanning and tawing leather.

Under the denomination of works of public and domestic utility are described gas-works, light-houses, warming and ventilating manufactories, public sewers, iron wharfs, and water-works.

In a subsequent division are described various mechanical processes in metals, as button-making, coining, clock and watch making, gun-making, founding, nail, needle, and pin making, wire-drawing, &c.

The next division relates to the manufacture of fibrous materials, as cotton, flax, silk, woollen, worsted, &c., hat-making, rope-making, and paper-making; and under the head of Miscellaneous Mechanical Processes, are included all such as could not be with propriety given under any of the preceding divisions, such as printing by presses and by

machines, copper-plate and lithographic printing, sculpture, lens and specula grinding, &c.; and, lastly, malting, distilling, biscuit-making by machinery, porter-brewing, &c.

Such is the arrangement which has been adopted in the following pages. How far it has been judicious, must be left to the judgment of others; but, at all events, the alphabetical index will furnish the reader with a ready means of reference; and it is to be hoped he will seldom be disappointed in finding any article which may reasonably be expected to be found in a work bearing the title given to the present volume. As far as lay in our power we have endeavoured to describe the most modern and effective machinery; but we do not flatter ourselves that this has always been done, although we have been most liberally assisted by many proprietors of extensive works, and by the Government Departments in particular. We ought also to acknowledge the aid we have received from different periodical Works, especially from the *Transactions of the Society of Arts*, and from the *Repertory of Arts*.

The practical mechanic will not expect to find in a general Work of this kind such minutiae of delineation as to furnish working drawings of the several machines described, because every such person will be aware of the great extent to which the Work must have been carried to have effected this object, or of the necessity we should have been under of suppressing a great deal of interesting popular matter, and thereby changing altogether the original design of the undertaking, which was to exhibit to the general reader a popular but correct idea of the nature of the processes by means of which our Manufactures have attained to their present state of pre-eminence, with a concise statistical view of their effects on the population, the wealth, and revenue of the British Empire.

The practical mechanic will not expect to find in a general Work of this kind such a minute of delineation as to furnish working drawings of the several machines described, because every such person will be aware of the great extent to which the Work must have been carried to have effected this object, or of the necessity we should have been under of suppressing a great deal of interesting popular matter, and thereby changing altogether the original design of the undertaking, which was to exhibit to the general reader a popular but correct idea of the nature of the processes by means of which our Manufactures have attained to their present state of pre-eminence, with a concise statistical view of their effects on the population, the wealth, and revenue of the British Empire.

MANUFACTURES

SECTION I.

ON THE GENERAL PRINCIPLES WHICH REGULATE THE APPLICATION OF MACHINERY TO MANUFACTURES AND THE MECHANICAL ARTS.

CHAPTER I.

ON THE MECHANICAL PRINCIPLES.

Manu-
factures.

Sect. I

THERE is, perhaps, no single circumstance which distinguishes our Country so remarkably from all others, as the vast extent to which we have carried our contrivances of Tools and Machines for forming all those conveniencies, of which so large a quantity is consumed by almost every class of the community. The amount of patient thought, of repeated experiment, of happy exertion of genius, by which our Manufactures have been created and carried to their present excellence, is scarcely to be imagined. If we look around the rooms we inhabit, or through those storehouses of every convenience, of every luxury that man can desire, which deck the crowded streets of our larger cities, we shall find in the history of each article, of every fabric, a series of failures which have gradually led the way to excellence; and we shall notice, in the Art of making even the most insignificant, processes calculated to excite our admiration by their simplicity, or to rivet our attention by their unlooked-for results.

The accumulation of skill and science which has been directed to diminish the difficulty of the production of Manufactured goods, has not been beneficial to that Country only in which it is concentrated; distant Kingdoms have participated in its advantages. The luxurious natives of the East,* and the ruder inhabitants of the African desert, are alike indebted to our looms. The produce of our factories seems to have preceded even our most enterprising travellers.† The cotton of India is conveyed by British ships round

* "The Bandana handkerchiefs manufactured at Glasgow have long superseded those which are genuine, and are now consumed in large quantities both by the natives and Chinese." Crawford's *Indian Archipelago*, vol. iii. p. 505.

† Captain Clapperton, when on a visit at the Court of the Sultan Bello, states, "provisions were regularly sent me from the Sultan's table on pewter dishes with the London stamp, and I even had a piece of meat served up on a white wash-hand basin of English manufacture." Clapperton's *Journey*, p. 88.

Manu-
factures.

half our Planet, to be woven by British skill in the factories of Lancashire. It is again set in motion by British capital, and, transported to the very plains whereon it grew, it is repurchased by the lords of the soil which gave it birth, at a cheaper price than that at which their coarser machinery will enable them to Manufacture it themselves.*

Sect. I.

We propose, in the present division of this work, to give a detailed account of the various Manufactures which are carried on in this Country, and a description of the Tools and Machinery by which their operations are conducted. Previously to this, however, we shall endeavour to state the principles on which their success depends, and to trace both the causes and the consequences of the application of machinery to supersede the skill and power of the human arm.

Advantages
of machi-
nery and
manufac-
tures.

1. The utility of Machinery and Manufactures seems to arise from *the addition which they make to human power ;—the economy of human time ;—and the conversion of substances apparently the most common and most worthless into valuable products.*

With respect to the first of these effects, the forces derived from wind, from water, and from steam, present themselves to the mind of every one ; these are, in fact, additions to human power, and will be considered in a future page : there are, however, other sources of its increase, by which the animal force of the individual is made to act with far greater than its unassisted powers, and to these we shall at present confine our observations.

The construction of Palaces, of Temples, and of Tombs, seems to have occupied the earliest attention of Nations just entering on the career of civilisation ; and the enormous blocks of stone moved from their native repositories to minister to the grandeur or piety of the builders, have remained to excite the astonishment of their posterity, even long after the purposes of many of these records, as well as the names of their founders, have been forgotten.

The different degrees of force necessary to move these ponderous masses will have varied according to the Mechanical knowledge of the people employed in their transport ; and that the extent of power required for this purpose is widely different under different circumstances, will appear from the following experiment, which is related by M. Redelet, *Sur L'Art de Bâtir*. A block of squared stone was taken for the subject of experiment, weighing 1080 lbs.

	lbs.
1. Weight of stone	1080
2. In order to drag this stone along the floor of the quarry roughly chiselled, it required a force equal to	758
3. The same stone dragged over a floor of planks required	652
4. The same stone placed on a platform of wood and dragged over a floor of planks, required	606
5. After soaping the two surfaces of wood which slid over each other it required	182
6. The same stone was now placed upon rollers of three inches diameter, when it required to put it in motion along the floor of the quarry	34

* At Calicut, in the East Indies, (whence the cotton cloth called *Calico* derives its name,) the price of labour is *one-seventh* of that in England, yet the market is supplied from British looms.

Manu-
factures.

6. To drag it by these rollers over a wooden floor required	lbs. 28
7. When the stone was mounted on a wooden platform, and the same rollers placed between that and a plank floor, it required	22

Sect. I.

From this experiment it results, that the force necessary to move a stone along the smoothed floor of its quarry is nearly two-thirds of its weight; to move it along a wooden floor, three-fifths; by wood upon wood, five-ninths; if the wooden surfaces are soaped, one-sixth; if rollers are used on the floor of the quarry, it requires one thirty-second part of the weight; if they roll over wood, one-fortieth; and if they roll between wood, one-fiftieth of its weight.

At each increase of knowledge, as well as on the contrivance of every new Tool, human labour becomes abridged. The man who contrived rollers, invented a Tool by which his power was quintupled. The workman who first suggested the employment of soap, or grease, was immediately enabled to move, without exerting a greater effort, more than three times the weight he could before. So sensible are the effects of grease in diminishing friction, that the drivers of sledges in Amsterdam, on which heavy goods are transported, carry in their hand a rope soaked in tallow, which they throw down from time to time before the sledge, in order that by passing over the rope it may become greased.

2. The next use of Machinery and Manufactures is—*the economy which they produce of human time.* So extensive and important is this effect, that we might, if we were inclined to generalize, embrace almost all their advantages under this one head; but the elucidation of principles of less extent will contribute more readily to a knowledge of the subject, and as numerous examples will be presented to the reader in the ensuing pages, we shall restrict our illustrations upon this point.

The Art of using the diamond for cutting glass has undergone, within a few years, a very important improvement. A glazier's apprentice, when using a diamond set in a conical ferrule, as was always the practice about twelve years since, found great difficulty in acquiring the Art of employing it with certainty, and at the end of a seven years' apprenticeship many were found but indifferently skilled in its use. This arose from the difficulty of finding the precise angle at which the diamond cut, and of guiding it along the glass at the proper inclination when that angle was found. Almost the whole of the time consumed, and of the glass destroyed in acquiring the Art of cutting glass, may now be saved by the use of an improved tool. The gem is set in a small piece of squared brass, with its edge nearly parallel to one side. A person skilled in its use now files away one side of the brass, until, by trial, he finds that it will act well, when guided, by keeping this edge pressed against a ruler. The diamond and its mounting are now attached to a stick similar to a pencil, by means of a swivel allowing a small angular motion. Thus the merest tyro, using it in this form, at once applies it at the proper angle, by pressing the side against a ruler; and even though the part he holds in his hand should deviate a little from its proper angle, it communicates no irregularity to the position of the diamond, which rarely fails to do its office when thus employed.

As another example of the economy of time, the use of gunpowder in blasting

Manu-
factures.

rocks may be noticed. Several pounds of that substance may be purchased for a sum acquired by a few days' labour; yet when this is employed for the purpose alluded to, effects are frequently produced which could not, even with the best tools, be accomplished by other means in less than many months. Sect. 1.

Prussiate of
potash.Old tin-
ware.

3. *Instances of the production of valuable matter from the most worthless materials* are constantly occurring. The skins used by the gold-beater are produced from the offal of animals. The hoofs of horses and cattle, and other horny refuse, are employed in the production of the Prussiate of Potash, that beautiful, yellow, crystallized salt, which is exhibited in the shops of some of our chemists. The worn-out sauce-pans and tin-ware of our kitchens, when beyond the reach of the tinker's Art, are not utterly worthless. We sometimes meet carts loaded with old tin kettles and iron coal-scuttles traversing our streets. These have not yet completed their useful course; the less corroded parts are cut into strips, punched with small holes, and varnished with a coarse black varnish, for the use of the trunk-maker, who protects the edges and angles of his boxes with them; the remainder are conveyed to the Manufacturing chemists in the out-skirts of the town, who employ them, in conjunction with pyroligneous acid, in making a black die for the use of Calico printers.

The difference between a Tool and a Machine is not capable of very precise distinction, nor is it necessary, in our popular explanation of them, to limit very strictly their popular sense. A Tool is usually more simple than a Machine; it is generally used with the hand, whilst a Machine is frequently moved by animal or steam power. The simpler Machines are often merely one or more Tools placed in a frame, and acted on by any moving power. In pointing out the advantages of Tools, we shall commence with some of the simplest.

Longitudi-
nal arrange-
ment of
needles

To arrange twenty thousand needles thrown promiscuously into a box, mixed and entangled with each other in every possible direction, in such a form that they shall be all parallel to each other, would, at first sight, appear a most tedious occupation; in fact, if each were to be separated individually, many hours must be consumed in the process. Yet this is an operation which must be performed many times in the Manufacture of needles; and it is accomplished in a few minutes by a very simple Tool, which is, in fact, nothing more than a small flat tray of sheet iron, slightly concave at the bottom. The needles are placed in it and shaken in a peculiar manner, by throwing them up a very little, and giving at the same time a slight longitudinal motion. The shape of the needles assists their arrangement; for if the needles cross each other, (unless, which is exceedingly improbable, they happen to be precisely the same,) they will, when they fall on the bottom of the tray, tend to place themselves side by side, and the hollow form of the tray assists this disposition. As they have no projection in any part to impede this tendency, or to entangle each other, they are, by continually shaking, arranged lengthwise, in three or four minutes. The direction of the shake is now changed, the needles are but little thrown up, but the tray is shaken endways; the result of which is, that in a minute or two the needles which were previously arranged endways become heaped up in a wall, with their ends against the extremity of the tray.

Manu-
factures.

They are now removed by hundreds at a time, by raising them with a broad iron spatula, on which they are retained by the fore-finger of the left hand. Sect. I.

Another process in the same Manufacture furnishes an example of one of the simplest contrivances which can come under the denomination of a Tool. After the needles have been arranged in the manner just described, it is necessary to separate them into two parcels, in order that their points may be all in one direction. This is usually done by women and children. The needles are placed sideways in a heap, on a table, in front of each operator, just as they are arranged by the process above described. From five to ten are rolled towards this person by the fore-finger of the left hand; this separates them a very small space from each other, and each in its turn is pushed lengthwise to the right or to the left, according as its eye is on the right or the left hand. This is the usual process, and in it every needle passes individually under the finger of the operator. A small alteration expedites the process considerably; the child puts on the fore-finger of its right hand a small cloth cap or finger-stall, and rolling from the heap from six to twelve needles, it keeps them down by the fore-finger of the left hand; whilst it presses the fore-finger of the right hand gently against the ends of the needles, those which have their points towards the right hand stick into the finger-stall; and the child, removing the finger of the left hand, allows the needles sticking into the cloth to be slightly raised, and then pushes them towards the left side. Those needles which had their eyes on the right hand do not stick into the finger cover, and are pushed to the heap on the right side previous to the repetition of this process. By means of this simple contrivance each movement of the finger, from one side to the other, carries five or six needles to their proper heap; whereas, in the former method, frequently only one was moved, and rarely more than two or three were transported at one movement to their place. Arranging the points in the same direction.

There occur operations in the Arts in which the assistance of an additional hand would be a great convenience to the workmen, and in these cases Tools or Machines of the simplest kind come to our aid. Vices of different forms, in which the material to be wrought is firmly grasped by screws, are used in almost every workshop; but a more striking example may be found in the trade of a nail-maker.

Some kinds of nails, such as those used for defending the soles of coarse shoes, called Hob-nails, require a particular form of the head, which is made by the stroke of a die. The workman holds the red-hot rod of iron out of which he forms them in his left hand; with his right hand he hammers the end of it into a point, and, cutting a proper length almost off, bends it nearly at right angles. He puts this into a hole in a small stake-iron immediately under a hammer connected with a treadle, and which has sunk in its surface a die corresponding to the intended form of the head; and having given one part of the form to the head by the small hammer in his hand, he moves the treadle with his foot, which disengages the other hammer, and completes the figure of the head: the returning stroke of this hammer strikes the finished nail out of the hole in which it was retained. Without this substitution of his foot for another hand, the workman would, probably, be obliged to heat the nails twice over. Hob-nails.

Manu-
factures.

Sect. I.

Another, although, fortunately, a less general use of Tools for human hands, is to assist the labour of those who are deprived by Nature, or by accident, of some of their limbs. Those who have examined the beautiful contrivances for the Manufacture of shoes by Machinery, which we owe to the fertile invention of Mr. Brunell, must have noticed many instances in which the operatives were enabled to execute their work with precision, although labouring under the disadvantages of the loss of an arm or a leg. A similar instance occurs at Liverpool, at the Institution for the Blind, where a Machine is used by those afflicted with blindness, for weaving sash-lines; it is said to have been the invention of a person suffering under that calamity. Other instances might be mentioned of contrivances for the use, the amusement, or the instruction of the wealthier classes, who labour under the same natural disadvantages. These triumphs of skill and ingenuity deserve a double portion of our admiration when applied to mitigate the severity of natural or accidental misfortune, when they supply the rich with occupation and knowledge, when they relieve the poor from the additional evils of poverty and want.

There exists a natural, although, in point of number, a very unequal division amongst Machines; they may be classed as *those which are employed to produce power*, and as *those which are intended merely to transmit power and execute work*.

The first of these divisions is of great importance, and is very limited in the variety of its species, although some of those species consist of numerous individuals.

Relation of
power to
time.

Of that class of Mechanical agents by which motion is transmitted, the lever, the pulley, the wedge, and many others, it has been demonstrated, that no power is gained by their use, however combined. *Whatever force is applied at one part can only be exerted at some other, diminished by friction and other incidental causes*; and it has been further proved, that *whatever is gained in the rapidity of execution is compensated by the necessity of exerting additional force*.

These two principles, long since placed beyond the reach of doubt, cannot be too constantly borne in mind; and in limiting our attempts to things which are possible, we are still, as we hope to show, possessed of a wide field of inexhaustible research, and of advantages derived from Mechanical skill, which have but just begun their influence on our Arts, and may be pursued without limit,—contributing to the improvement, the advantage, and the happiness of our race.

The Earth's
rotation
the source
of power.

Of those Machines by which we produce power, it may be observed, that although they are to us immense acquisitions, yet in regard to two of them, the powers of wind and water, we merely make use of bodies in a state of motion by Nature; we change their directions in order to render them subservient to our purposes, but we neither add to nor diminish the quantity of motion in existence. When we expose the sails of a wind-mill obliquely to the gale, we check the velocity of a small portion of the atmosphere, we convert its own rectilinear motion into one of rotation in the sails; we thus change the direction of force, but we create no power. The same may be observed with regard to the sails of a vessel; the quantity of motion given to it is precisely the same as that which is destroyed in the atmosphere.

If we avail ourselves of a descending stream to turn a water-wheel, we are appro-

Manu-
factures.

Sect. I.

priating a power which Nature may appear, at first sight, to be uselessly and irreco-
verably wasting, but which, upon due examination, we shall find she is ever repairing
by other processes. The fluid which is falling from a higher to a lower level, carries
with it the velocity due to its revolution with the Earth at a greater distance from its
centre. It will therefore accelerate, although to an almost infinitesimal extent, the
Earth's daily rotation.

The sum of all these increments of velocity, arising from the descent of all the rivers
on the Earth's surface, would in time become perceptible, did not Nature, by the process
of evaporation, raise the waters back to their sources; and thus again, by removing
matter to a greater distance from the centre, destroy the velocity generated by its
previous approach.

The force of vapour is another fertile source of moving power, but even in this it
cannot be maintained that power is created. Water is converted into elastic vapour by
the combustion of fuel. The Chemical changes which take place are constantly increasing
the atmosphere by large quantities of carbonic acid and other gases noxious to animal
life. By what process Nature decomposes or reconverts these elements into a solid
form, is not sufficiently known. The absorption in large quantities of one portion of
them by vegetation is stated to take place; but if the end could be accomplished by
Mechanical force, it is probable the power necessary to produce it would at least equal
that which was generated by the original combustion. Man, therefore, cannot create
power; but, availing himself of his knowledge of Nature's mysteries, he applies his
talents to diverting a small and limited portion of her energies to his own wants; and,
whether he employs the regulated action of steam, or the more rapid and tremendous
effects of gunpowder, he is only producing, in small quantity, compositions and decom-
positions which Nature is incessantly at work in reversing, for the restoration of that
equilibrium, which we cannot doubt is constantly maintained throughout even the
remotest limits of our system.

The operations of Man participate in the character of their author; they are diminutive,
but energetic during the short period of their existence; those of Nature, acting over
vast spaces, and unlimited by time, are ever pursuing their silent and resistless career.

In stating the broad principle, that all combinations of Mechanical contrivances can
only augment the force communicated to the Machine at the expense of the time
employed in producing the effect, it might, perhaps, be imagined, that the assistance
derived from such contrivances is small. This is, however, by no means the case: the
almost unlimited variety they afford enables us to exert to the greatest advantage the
forces we employ. Although there is a limit beyond which it is impossible to reduce
the power necessary to produce any given effect, yet it seldom happens that the methods
first employed at all approach that limit. In dividing the knotted root of a tree for the
purposes of fuel, how very different will be the time consumed according to the nature
of the Tool made use of. The hatchet, or the adze, will divide it into small parts, but
will consume a large portion of the workman's time. The saw will answer the same
purpose more effectually and more quickly; this, in its turn, is superseded by the wedge,

Manu-
factures.

which rends it in a still shorter time. If the circumstances are favourable, and the workman skilful, the time and expense may be still further reduced by the use of a small quantity of gunpowder exploded in holes judiciously placed in the block. Sect. I.

Packing and
transport of
cotton.

When a mass of matter is moved a certain force must be expended, and upon the proper economy of this the price of transport depends. A Country must, however, have reached a high degree of civilisation before it will have approached this limit. The cotton of Java is carried in junks to the coast of China, but from the circumstance of the seed not being previously separated, three quarters of the weight is not cotton. This might, perhaps, be justified by the want of Machinery to separate it in Java, or by the relative cost of the operation in the two Countries. But the cotton itself, as packed by the Chinese, occupies three times the bulk of an equal quantity shipped by Europeans for their own markets. Thus the freight of a given quantity of cotton costs the Chinese nearly twelve times the price to which, by a proper attention to Mechanical methods, it might be reduced.*

We shall now offer to our readers a general view of the various advantages which result from the use of Machinery.

I. OF ACCUMULATING POWER.

Fly neces-
sary in
rolling iron.

Whenever the work to be done requires more force for its execution than can be generated in the time necessary for its completion, recourse must be had to some Mechanical method of preserving and condensing a part of the power exerted previously to the commencement of the process. This is most frequently accomplished by a fly-wheel, which is in fact nothing more than a wheel having a very heavy rim, so that the greater part of its weight is near the circumference. It requires great power applied for some time to set this in rapid motion, and when moving with considerable velocity, if its force is concentrated on a point, its effects are exceedingly powerful. In some of the iron-works, where the power of the steam-engine is a little too small for the rollers which it drives, it is usual to set it at work a short time before the red-hot iron is ready to be removed from the furnace to the rollers, and to allow it to work with great rapidity until the fly has acquired a velocity rather alarming to those unused to such establishments. On passing the softened mass of iron through the first groove, the engine receives a great and very perceptible check, and its speed is diminished at the next and at each succeeding passage, until the iron bar is reduced to such a size that the ordinary power of the engine is sufficient to roll it.

Also in
punching
plate iron.

The powerful effect of a large fly-wheel when its force can be concentrated in a point, was curiously illustrated at one of the largest of our Manufactories of steam-engines. The proprietor was showing to a friend the method of punching holes in iron plates for the boilers of steam-engines. He held in his hand a piece of sheet iron three-eighths of an inch thick, which he placed under the punch; observing, after several holes had been made, that the punch made its perforations more and more slowly, he called to the

* Crawford's *Indian Archipelago*.

Manu-
factures.

engine-man to know what made the engine work so sluggishly, when it was found that the fly-wheel and punching apparatus had been detached from the steam-engine just at the commencement of his experiment.

Sect. I.

Another mode of accumulating power arises from lifting a weight and then allowing it to fall. A man even with a heavy hammer might strike repeated blows upon the head of a pile without producing any effect. But if he raises a much heavier hammer to a much greater height, its fall, though far less frequently repeated, will produce the desired effect.

II. OF THE REGULATING POWER.

Uniformity and steadiness in the rate at which Machinery works are essential both for its success and its duration.

The beautiful contrivance of Mr. Watt, who invented the *governor* of the steam-engine, must immediately occur to all who are familiar with that admirable Machine: as it will be fully described in another part of this work we need at present only allude to it.

The regularity of the supply of fuel to the fire under the boilers of steam-engines contributes to the uniformity of their rate, and also economises the consumption of coal. Several patents have been taken out for methods of regulating this supply. The general principle is to make the engine supply the fire by means of a hopper, with small quantities of fuel at regular intervals, and to diminish this supply when it works quickly. One of the incidental advantages of this plan is, that by throwing on a very small quantity of coal at a time, the smoke is almost entirely consumed.

The dampers of ashpits and chimneys are in some cases connected with Machines in order to regulate their speed.

Another contrivance for regulating the effect of Machinery consists in a vane, or a fly of little weight but presenting a large surface. This revolves rapidly, and soon acquires a uniform rate, which it cannot greatly exceed; because any addition to its velocity produces a much greater addition to the resistance which it meets with from the air. The interval between the strokes on the bell of a clock is regulated by this means; and the fly is so contrived, that this interval may be altered by presenting the arms of it more or less obliquely to the direction in which they move.

This kind of fly, or vane, is generally used in the smaller pieces of Mechanism, and, unlike the heavy fly, it is a destroyer instead of a preserver of force. It is the regulator used in musical boxes, and in almost all Mechanical toys.

Another very beautiful contrivance for regulating the number of strokes made by a steam-engine is used in Cornwall, it is called the *cataract*, and depends on the time required to fill a vessel plunged in water, the valve through which the fluid is admitted being adjustable at the will of the engine-man.

III. INCREASE OF VELOCITY.

The fatigue produced on the muscles of the human frame does not altogether depend on the actual force exerted at each effort, but partly on the frequency with which it is exerted. The exertion necessary to accomplish every operation consists of two parts: one of these is the propulsion of the Tool or instrument used; and the other is the motion of some limb of the animal producing the action. If we take as an example the act of driving a nail into a piece of wood, one of these is, the *propelling* the hammer head against the nail; the other is, *raising* the arm in order to lift the hammer. If the weight of the hammer is considerable, this *latter* part will cause the greatest portion of the exertion. If the hammer is light, the exertion of *raising* the arm will produce the greatest part of the fatigue. It does therefore happen, that operations requiring very trifling force, if frequently repeated, will tire more effectually than more laborious work. There is also a degree of rapidity beyond which the action of the muscles cannot be pressed.

Tags for
boot-laces.

It is of considerable importance for the economy of labour, to adjust the weight of that part of the animal's body which is moved, the weight of the Tool it urges, and the frequency of repetition of these efforts, so as to produce the greatest effect. An instance of the saving of time by making the same motion of the arm execute two operations instead of one, occurs in the simple Art of making the tags of boot-laces; they consist, as is well known, of very thin, tinned, plate iron, and used to be cut out of long strips of that material into pieces of such a breadth that when bent round they just enclosed the lace. Two pieces of steel have recently been fixed to the side of the shears, by which each piece of tin as soon as it is cut is bent into a semi-cylindrical form. The additional power required for this operation is almost insensible, and it is executed by the same motion of the arm which produces the cut. This work is usually performed by women and children, and with the improved Tool more than three times the quantity is produced in a given time.* Whenever the work is itself light it becomes necessary, in order to economise time, to increase the velocity. Twisting the fibres of wool by the fingers would be a most tedious operation: in the common spinning-wheel the velocity of the foot is moderate, but by a very simple contrivance that of the thread is most rapid. A piece of cat-gut passing round a large wheel and then round a small spindle effects this change. This contrivance is common to a multitude of Machines, some of them very simple. In large shops for the retail of ribands it is necessary at short intervals to "take stock," that is, to measure and rewind every piece of riband, an operation which, even with this mode of shortening it, is sufficiently tiresome, but which without it would be almost impossible from its expense. The small balls of sewing cotton, so cheap and so beautifully wound, are formed by a machine on the same principle, and but a few steps more complicated.

* See *Transactions of the Society of Arts*, 1826.

Manu-
factures.

Sect. I.

In turning from the smaller instruments in frequent use to the larger and more important Machines, the economy of increasing the velocity becomes more striking. In converting cast into wrought iron, a mass of metal of about a hundred weight is heated almost to a white heat, and placed under a heavy hammer moved by water or steam power. This is raised by a projection on a revolving axis; and if the hammer only derived its momentum from the space through which it fell, it would require a considerably greater time to give a blow. But as it is important that the softened mass of red-hot iron should receive as many blows as possible before it cools, the form of the *cam* or projection on the axis is such, that instead of *lifting* the hammer to a small height it throws it up with a jerk, and almost the instant after it strikes against a large beam, which acts as a powerful spring, and impels it down on the iron with great velocity; by this means about double the number of strokes can be made in a given time. In the smaller tilt-hammers this is carried still further: by striking the tail of the tilt-hammer forcibly against a small steel anvil, it rebounds with such velocity, that from three to five hundred strokes are made in a minute.

Velocity of
strokes of
tilt-ham-
mers.

In the Manufacture of anchors, an Art in which this system is of still greater importance, it has only been applied recently.

IV. DIMINUTION OF VELOCITY.

The most frequent reason for employing contrivances for diminishing velocity, arises from the necessity of overcoming great resistances with small power.

Systems of pulleys, the crane, and many other illustrations present themselves, which more strictly belong to others of the causes which we have assigned for the advantages of Machinery.

The common smoke-jack is an instrument in which the velocity communicated is too great for the purpose required, and it is transmitted through wheels which reduce it to a more moderate rate.

Smoke-jack

V. SPREADING THE ACTION OF A FORCE EXERTED FOR A FEW MINUTES OVER A LARGE TIME.

This is one of the most common and most useful of the employments of Machinery. The half minute which we daily devote to the winding up of our watches is an exertion of labour almost insensible, yet by the aid of a few wheels its effect is spread over the twenty-four hours. In our clocks this extension of the time of action of the original force impressed is carried still further; the better kind usually require winding up once in eight days, and some are occasionally made to continue in action during a month, or even a year. Another familiar illustration may be noticed in our domestic furniture: the common jack by which our meat is roasted, is a contrivance to enable the cook in a few minutes to exert a force which the Machine retails out during the

Common
jack.

Manu-
factures.

succeeding hour in turning the loaded spit: thus enabling her to bestow her undivided attention on her other duties. A great number of automata and other Mechanical toys moved by springs may be classed under this division.

Sect. I.

VI. SAVING TIME IN NATURAL OPERATIONS.

The process of Tanning will furnish us with a striking illustration of the power of Machinery in producing this effect. The object of the Art is to combine a certain Tanning principle with every particle of the skin to be tanned. This, in the ordinary process, is accomplished by allowing the skins to soak in pits containing a solution of Tanning matter; they remain in the pits six, twelve, or eighteen months, and in some instances (if the hides are very thick) they are exposed to the operation for two years, or even during a longer period. This length of time seems to be required in order to allow the Tanning matter to penetrate into the interior of a thick hide.

Tanning in
vessels ex-
hausted of
air.

The improved process consists in placing the hides with the solution of Tan in close vessels, and then exhausting the air. The effect of this is to withdraw any air which might be contained in the pores of the hides, and to employ the pressure of the atmosphere to aid capillary attraction in forcing the Tan into the interior of the skins. The effect of the additional force thus brought into action can be equal only to one atmosphere, but a further improvement has been made: The vessel containing the hides is, after exhaustion, filled up with a solution of Tan; a small additional quantity is then injected with a forcing pump. By these means any degree of pressure may be given which the containing vessel is capable of supporting; and it has been found, that by employing such a method the thickest hides may be Tanned in six weeks or two months.

The operation of Bleaching linen in the open air is one for which considerable time is necessary, and although it does not require much labour, yet from the risk of damage and of robbery from long exposure, a mode of shortening the process was highly desirable. The method now practised, although not Mechanical, is such a remarkable instance of the application of Science to the practical purposes of Manufactures, that in mentioning the advantages derived from shortening natural operations, it would have been scarcely pardonable to omit alluding to the beautiful application of chlorine in combination with lime to processes of Bleaching.

Making salt.

Another instance more strictly Mechanical occurs in some Countries where fuel is expensive, and the heat of the Sun is not sufficient to evaporate the water from brine springs. It is first pumped up to a reservoir, and then allowed to fall in small streams through fagots. Thus it becomes divided, and, presenting a large surface, evaporation is facilitated, and the brine which is collected in the vessels below the fagots is stronger than that which was pumped up. After thus getting rid of a large part of the water, the remaining portion is driven off by boiling. The success of this operation depends on the circumstance of the atmosphere not being saturated with moisture: if the air, at the

Manu-
factures.

Sect. I.

time during which the brine falls through the fagots, holds in solution as much moisture as it can contain in an invisible state, none can be absorbed from the salt water, and the labour expended in pumping is entirely wasted. The state of the air, as to dryness, is therefore an important consideration in fixing the time at which this operation is to be performed; and an attentive examination of its state, by means of the Hygrometer, might be productive of some economy of labour.

VII. EXERTING FORCES TOO LARGE FOR HUMAN POWER.

It requires some skill and a considerable apparatus to enable many men to exert their whole force at a given point, and when this number amounts to hundreds or to thousands additional difficulties present themselves. If ten thousand men were hired to act simultaneously, it would be exceedingly difficult to discover whether each exerted his whole force, and consequently, to be assured that each man exerted the force for which he was paid. And if still larger bodies of men or animals were necessary, not only would the difficulty of directing them become greater, but the expense would increase from the necessity of transporting food for their subsistence.

In all our larger Manufactories numerous instances occur of the application of the power of steam to overcome resistances which it would require far greater expense to surmount by means of animal labour. The twisting of the largest cables, the rolling, hammering and cutting large masses of iron, the draining of mines, all require enormous exertions of physical force continued for considerable periods of time. Other means are had recourse to when the force required is great, and the space through which it is to act is small. The Hydraulic Press of Bramah can, by the exertion of one man, produce a pressure of 1500 atmospheres, and with such an instrument a cylinder of wrought iron three inches thick has been burst. In rivetting together the iron plates out of which-steam engine boilers are made, it is necessary to produce as close a joint as possible. This is accomplished by using the rivets red-hot; and while they are in that state the two plates of iron are rivetted together, and the contraction which the rivet undergoes in cooling draws them together with a force which is limited only by the tenacity of the iron of which the rivet itself is made.

Hydraulic
press.Rivetting
boilers.

VIII. EXECUTING OPERATIONS TOO DELICATE FOR HUMAN TOUCH.

It is not alone in the greater operations of the Engineer or the Manufacturer, that those vast powers which Man has called into action, in availing himself of the agency of steam, are fully developed. Wherever the individual operation, demanding little force for its own performance, is to be multiplied in almost endless repetition, commensurate power is required. It is the same "giant arm which twists the largest cable," that spins from the cotton plant an "almost gossamer thread." Obedient to the hand which called into action its resistless powers, it contends with the ocean and the storm, and rides triumphant through dangers and difficulties unattempted by the older modes of

Manu-
factures.

navigation.* It is the same engine that, in its more regulated action, weaves the canvass it may one day supersede, and, with almost fairy fingers, entwines the meshes of the most delicate fabric that adorns the female form.†

Sect. I.

Wetting
Bank-note
paper.

The process of printing on silver paper, which is necessary for Bank-notes, is attended with some inconvenience, from the necessity of damping the paper previously to taking the impression. It was difficult to do this uniformly; and in the old process of dipping a parcel of several sheets together into a vessel of water, the outside sheets, getting much more wet than the others, were very apt to be torn. A method has been adopted at the Bank of Ireland which obviates this inconvenience. The whole quantity of paper to be damped is placed in a close vessel from which the air is exhausted; water is then admitted and every leaf is completely wetted; the paper is then removed to a press, and all the superfluous moisture is squeezed out.

IX. REGISTERING OPERATIONS.

Counting
machines.

One of the singular advantages we derive from Machinery is in the check which it affords against the inattention, or the idleness, of human agents. Few occupations are more wearisome than counting a series of repetitions of the same fact; the number of paces we walk affords a tolerably good measure of distance passed over, but the value of this is much enhanced by possessing an instrument, the Pedometer, which will count for us the number we have made. An instrument similar in its object, but differing in its construction, has been used for counting the number of strokes made by a steam-engine, and the number of coins struck in a Press.

* The Fifth Report of the Select Committee of the House of Commons on the Holyhead Roads furnishes ample proof of the great superiority of steam-boats over sailing vessels. The following extracts are taken from the evidence of Captain Rogers, the commander of one of the packets.

Question. Be so good as to acquaint the committee in what manner the communication has been kept open between Holyhead and Dublin by steam-packets, and what has been the success of the experiment of establishing them on that station.

Answer. We have done every thing that could be done, *by steam-boats*; and they will go, no doubt, when a sailing vessel will not,—that has been proved.

Quest. Are you not perfectly satisfied, from the experience you have had, that the steam-vessel you command is capable of performing what no sailing vessel can do?

Ans. Yes.

Quest. During your passage from Gravesend to the Downs could any square-rigged vessel, from a first-rate down to a sloop of war, have performed the voyage you did in the time you did it in the steam-boat?

Ans. No; it was impossible. In the Downs we passed several Indiamen, and 150 sail there that could not move down the Channel; and at the back of Dungeness we passed 120 more.

Quest. At the time you performed that voyage, with the weather you have described, from the Downs to Milford, if that weather had continued twelve months would any square-rigged vessel have performed it?

Ans. They would have been a long time about it; probably, would have been weeks instead of days. A sailing vessel would not have beat up to Milford, as we did, in twelve months.

† The importance and diversified applications of the steam-engine were most ably enforced in the speeches made at a Public meeting held June, 1824, for the purpose of proposing the erection of a monument to the memory of James Watt; these were subsequently printed.

Manu-
factures.

Sect. I.

Another instrument for registering is used in some establishments for calendering and embossing. Many hundred thousand yards of calicoes and stuffs pass weekly through these operations, and as the amount paid for the process is small, the time spent in measuring them would bear a considerable proportion to the profit. A Machine has been contrived for measuring and registering the length of the goods as they pass rapidly through the hands of the operator, and all chance of erroneous counting is thus avoided.

Perhaps the most useful contrivance of this kind, is one for ascertaining the vigilance of a watchman. It is a piece of Mechanism connected with a clock placed in an apartment to which the watchman has not access; but he is ordered to pull a string situated in a certain part of his round once in every hour. The instrument, aptly called a *tell-tale*, informs the owner whether the man has missed any, and what, hours during the night.

X. ECONOMY OF THE MATERIALS EMPLOYED.

The precision with which all operations by Machinery are executed, and the exact similarity of the articles thus made, produce a degree of economy in the consumption of the raw material which is in some cases of great importance.

The earliest mode of cutting the trunk of a tree into planks, was by the use of the hatchet or the adze. It might, perhaps, be first split into three or four portions, and then each portion was reduced to a uniform surface by those instruments. With such means the quantity of plank produced would probably not equal the quantity of the raw material wasted by the process, and, if the planks were thin, would certainly fall far short of it. An improved Tool, the saw, completely reverses the case: in converting a tree into thick planks it causes a waste of a very small fractional part; and even in reducing it to planks of only an inch in thickness, it does not waste more than an eighth part of the raw material.

The rapid improvements which have taken place in the Printing Press during the last twenty years, afford another instance of saving in the materials consumed, which is interesting from its connection with Literature, and valuable because admitted and well ascertained by measurement.

In the old method of inking type, by large hemispherical balls stuffed and covered with leather, the printer, after taking a small portion of ink from the ink-block, was continually rolling them in various directions against each other, in order that a thin layer of ink might be uniformly spread over their surface. This he again transferred to the type by a kind of rolling action. In such a process, even admitting considerable skill in the operator, it could not fail to happen that a large quantity of ink should get near the edges of the balls, which, not being transferred to the type, became hard and useless, and was taken off in the form of a thick black crust. Another inconvenience also arose,—the quantity of ink spread on the block not being regulated by measure, and the number and direction of the transits of the inking balls over each other depending on

Mode of
spreading
ink on type.

Manu-
factures.

Sect. I.

the will of the operator and being irregular, it was impossible to place on the type a uniform layer of ink, of exactly the quantity sufficient for the impression. The introduction of cylindrical rollers of an elastic substance, formed by the mixture of glue and treacle, superseded the inking balls, and produced considerable saving in the consumption of ink:—but the most perfect economy was to be produced only by mechanism.

When Printing Presses moved by the power of steam were introduced, the action of these rollers was found well calculated to be performed by the Machine, and a reservoir of ink was formed from which one roller regularly abstracted a small quantity at each impression. From three to five other rollers spread this portion uniformly over the slab (by most ingenious contrivances varied in almost each kind of Press,) and another travelling roller, having fed itself on the slab, passed and repassed over the type just previously to its giving the impression on the paper. The following is an account of the results of an accurate experiment made at one of the largest Printing establishments in the Metropolis. Two hundred reams of paper were printed off, the old method of inking with balls being employed; two hundred reams of the same paper, and for the same book, were then printed off in the Presses which inked their own type.

The consumption of ink by the Machine was to that by the balls as four to nine, or rather less than one-half.

In order to show that this plan of inking puts the proper quantity of ink upon the type, we must prove first that it is not too little:—this would soon have been discovered from the complaints of the Public and the Booksellers; and, secondly,—that it is not too much. This latter point is satisfactorily established by a reference to the frequency of change of what is called “the set-off sheet” in the old method. A few hours after one side of a sheet of paper has been printed upon, the ink is sufficiently dry to allow it to receive the impression upon the other, and as considerable pressure is made use of, the tympan on which the side first printed is laid, is guarded from soiling it by a sheet of paper called the set-off sheet. This paper receives in succession every sheet of the work to be printed, and acquires from them more or less of the ink, according to their dryness or the quantity upon them. It was usual in the former process, after about one hundred impressions, to change the set-off sheet, which in that time became too much soiled for further use. In the new method of printing by Machinery no set-off sheet is used, but a blanket is employed as its substitute: this does not require changing above once in five thousand impressions, and instances have occurred of its remaining sufficiently clean for twenty thousand. Here, then, is proof that the quantity of superfluous ink put upon the paper in Machine-printing is so small, that if multiplied by five thousand, and in some instances even by twenty thousand, it is only sufficient to render useless a single piece of clean cloth.*

* In the very best kind of printing it is necessary in the old method to change the set-off sheet once in twelve times. In printing the same kind of work by Machinery the blanket is changed once in 2000.

XI. THE IDENTITY OF THE WORK WHEN IT IS OF THE SAME KIND.

Nothing is more remarkable, and yet less unexpected, than the perfect identity of things manufactured by the same Tool. If the top of a box is to be made to fit over the lower part, it may be done by gradually advancing the tool of the sliding rest; the proper degree of tightness between the box and its lid being found by trial. After this adjustment, if a thousand boxes are made, no additional care is required; the tool is always carried up to the stop, and each box will be equally adapted to every lid.

The same identity pervades all the arts of Printing; the impressions from the same block, or the same copper plate, have a similarity which no labour could produce by hand. The minutest traces are transferred to all the impressions, and no omission can arise from the inattention or unskilfulness of the operator. The steel punch, with which the card wadding for a fowling-piece is cut, if it once perform its office with accuracy, constantly reproduces the same exact circle.

XII. ACCURACY OF THE WORK WHEN OF DIFFERENT KINDS.

The accuracy with which Machinery executes its work is, perhaps, one of its most important advantages: it may, however, be contended that a considerable portion of this advantage may be resolved into a saving of time.

It generally happens, that any improvement in tools increases the quantity of work done in a given time. Without tools, that is, by the mere efforts of the human hand, there are, undoubtedly, multitudes of things which it would be impossible to make. Add to the human hand the rudest cutting instrument, and its powers are enlarged: the fabrication of many things then becomes easy, and that of some possible with great labour. Add the saw to the knife or the hatchet, and other works become possible, and a new course of difficult operations is brought into view, whilst many of the former difficulties are removed. This observation is applicable even to the most perfect tools or machines. It would be *possible* for a very skilful workman with files and polishing substances to form a cylinder out of a piece of steel, but the time which this would require would be so considerable, and the number of failures would probably be so large, that for all practical purposes such a mode of producing a steel cylinder might be said to be impossible.

The same process by the aid of the lathe and the sliding rest is the every-day employment of hundreds of workmen.

It is more easy to make a good circle than to produce a straight line. Of all the operations of art, that of turning is the most perfect. If two surfaces are worked against each other, whatever may have been their figure at the commencement, there exists a tendency in them to become portions of spheres. Either of them may become convex, and the other concave, with various degrees of curvature. A plain surface is

Manu-
factures.

Sect. I.

the line of separation between convexity and concavity, and is most difficult to hit. A similar difficulty takes place in figuring specula for telescopes; the parabola is the surface which separates the hyperbolic from the elliptic figure, and is the most difficult to form. If a spindle not cylindrical at its end is pressed into a hole not circular, and if the spindle be kept constantly turning, there is a tendency in these two bodies so situated to become conical, or to have circular sections. If a triangular pointed piece of iron be worked round in a circular hole the edges will gradually wear, and it will become conical. These facts, if they do not explain, at least illustrate the principles on which the excellence of work formed in the lathe depends

The operation of printing the Numbers on Bank-notes is one which requires perfect accuracy; and although each Number differs from all the others, it is accomplished by a few wheels.

OF COPYING.

The two last sources of excellence in the work produced by Machinery depend on a principle which pervades a very large portion of all Manufactures, and is one upon which the cheapness of the articles produced seems greatly to depend. The principle to which we allude is the system of COPYING, taken in its most extensive sense. Almost unlimited pains are, in some instances, bestowed on the original, from which a series of Copies is to be produced; and the larger the number of these Copies, the more care and pains can the manufacturer afford to lavish upon the original. It may thus happen, that the instrument, or tool actually producing the work, shall cost five or even ten thousand times the price of each individual specimen of its power.

As the system of Copying is of so much importance, and of such extensive use in the Arts, we shall endeavour to classify a considerable number of those processes in which it is employed; not, however, pretending to give a complete list, and restricting ourselves to the shortest possible detail which will be consistent with a due regard to making the subject intelligible.

Operations of Copying take place under the following circumstances:—by Printing,—by Casting,—by Moulding,—by Stamping,—by Punching,—with elongation,—with altered dimensions.

OF COPYING BY PRINTING.

Of Copying by Printing.—The Art of Printing, in all its numerous departments, is essentially an Art of Copying. Under its two great divisions, Printing from hollow lines, as in copper-plate, and Printing from surface, are comprised numerous Arts.

Copper-
plate Print-
ing.

Copper-plate Printing.—In this instance the Copies are made by transferring by pressure a thick ink from the hollows and lines cut in the copper to sheets of paper. An artist will sometimes exhaust the labour of one or two years upon engraving a Plate, which will not, in some cases, furnish above five hundred Copies in a state of perfection.

Engraving on steel.—This is in most respects similar to engraving on copper, except that the number of Copies is far less limited. A Bank-note engraved as a copper-plate will not give above three thousand impressions without a sensible deterioration. Two impressions from a Bank-note engraved on steel were examined by one of the best artists of the present day, and he could not say, with any confidence, which was the earliest impression. One of these was a proof from amongst the first thousand, the other was taken after between seventy and eighty thousand had been printed off.

Sect. I.
Printing
from steel.

Music Printing.—Music is printed from Pewter Plates, on which the characters have been impressed by steel punches. The metal being much softer than copper is liable to scratches, which detain a small portion of the ink. This is the reason of the dirty appearance of printed music. A new process has recently been invented by Mr. Cowper, by which this inconvenience will be avoided. The improved method, which gives sharpness to the characters, is still an art of copying; but it is effected by surface Printing.

Music
Printing.

Calico Printing from cylinders.—Many of the patterns on printed calicoes are Copies by printing from copper cylinders about four or five inches in diameter, on which has been previously engraved the desired pattern. One portion of the cylinder is exposed to the ink, whilst an elastic scraper of stuffed leather, by being pressed forcibly against another part, removes all superfluous ink from the surface previous to its reaching the cloth. A piece of calico twenty-eight yards in length rolls through this press in four or five minutes.

Calico
Printing
from copper
cylinders.

Printing from perforated sheets of metal.—Very thin brass is sometimes perforated in the form of letters, usually a name; this is placed on any substance which it is required to mark, and a brush dipped in some paint is passed over the brass. Those parts which are cut away admit the paint, and thus a copy of the name appears on the substance below.

Stencilling.

This method, which affords rather a coarse copy, is sometimes used for paper with which rooms are covered, and more especially for the borders. If a portion is required to match an old pattern, this is, perhaps, the most economical way of producing it.

The beautiful red cotton handkerchiefs dyed at Glasgow have their pattern given to them by a process similar to this, except that instead of *printing* from a pattern the reverse operation, that of *discharging* a part of the colour from a cloth already dyed, is performed. A number of handkerchiefs are pressed with immense force between two plates of metal, which are similarly perforated with round or lozenge-shaped holes, according to the intended pattern. The upper plate of metal is surrounded by a rim, and a fluid which has the property of discharging the red dye is poured upon that plate. This liquid passes through the holes in the metal, and also through the calico; but owing to the great pressure opposite all the parts of the plates not cut away it does not spread itself beyond the pattern. After this the handkerchiefs are washed, and the Pattern of each is a copy of the perforated metal plate used in the process.

Patterns
on red cot-
ton handker-
chiefs.

The other department, or that of *Printing from surface*, is of more frequent application in the Arts.

Manu-
factures.
Wood-cuts.

Printing from wooden blocks.—A block of box-wood is in this instance the substance out of which the pattern is formed: the design being sketched upon it, the workman cuts away with sharp tools every part except the lines to be represented in the impression. This is exactly the reverse of the process of engraving on copper, in which every line to be represented is cut away. The ink instead of filling the cavities cut in the wood is spread upon the surface which remains, and is thence transferred to the paper.

Common
Printing.

Printing from movable type.—This is the most important in its influence of all the Arts of Copying. It possesses a singular peculiarity, which arises from the immense subdivision of the parts that form the pattern. After that pattern has furnished thousands of Copies, the same individual elements may be arranged again and again in other forms, and thus furnish multitudes of originals, from each of which thousands of their copied impressions may flow.

Stereotype
printing.

Printing from stereotype.—This mode of producing Copies is very similar to the preceding: but as the original pattern is incapable of change, it is applied only to cases where an extraordinary number of Copies are demanded, or where the work consists of figures, and it is of great importance to ensure accuracy. Individual alterations may be made in it; and thus Mathematical Tables may, by the gradual extirpation of error, at last become perfect. This mode of producing Copies possesses, in common with that by movable types, the advantage of being capable of being used in conjunction with wood-cuts, a union frequently of considerable importance, and which is not so readily accomplished with engravings on copper.

Printing
calico from
blocks.

Calico Printing from blocks.—This is a mode of Copying by surface Printing from the ends of small pieces of copper wire, of various forms, fixed into a block of wood. They are all of one uniform height, about the eighth part of an inch above the surface of the wood, and are arranged by the maker into any required pattern. If the block be placed upon a piece of fine woollen cloth, on which ink of any colour has been uniformly spread, the projecting copper wires receive a portion which they give up when applied to the calico to be printed. By the former method of Printing on calico, only one colour could be used; but by this plan, after the flower of a rose, for example, has been printed with one set of blocks, the leaves may be printed of another colour by a different set.

Printing
oil-cloth.

Printing Oil-cloth.—After the canvass, which forms the basis of oil-cloth, has been covered with paint of one uniform tint, the remainder of the processes, which it passes through, are a series of Copying by surface Printing from patterns formed upon wooden blocks very similar to those employed by the calico printer. Each colour requires a set of blocks; and thus those oil-cloths with the greatest variety of colours are most expensive.

There are several other varieties of Printing which we shall briefly notice as Arts of Copying; which although not strictly surface Printing, yet are more allied to it than to that from copper plates.

Letter copy-
ing.

Letter Copying.—In one of the modes of performing this process, a sheet of very thin paper is damped, and placed upon the writing to be copied. The two papers are then

Manu- passed through a rolling press, and a portion of the ink from one paper is transferred *Sect. I.*
factures, to the other. The writing is of course reversed by this process; but the paper to which
 it is transferred being thin, it is visible on the other side in an uninverted position.

Another common mode of Copying letters is by placing a sheet of paper covered on both sides with a black substance prepared from lamp-black, between a sheet of thin paper and the paper on which the letter to be despatched is to be written. If the upper or thin sheet be written upon with any hard pointed substance, the words written with this style will be impressed from the black paper upon both those adjoining it. The translucency of the upper sheet, in this instance, is necessary to obviate the inconvenience of the reversing of the writing. Both these Arts are very limited in their extent, two or three being the utmost number of repetitions they allow.

Printing on China.—This is an Art of Copying which is carried to a very great extent. *Printing on China.*
 As the surfaces to which the impression is to be conveyed are often curved, and sometimes even fluted, the ink, or paint, is first transferred from the copper to some flexible substance, such as paper, or an elastic compound of glue and treacle. It is almost immediately conveyed from this to the unbaked biscuit, to which it more readily adheres.

Lithographic Printing.—This is another mode of producing Copies almost unlimited in *Lithographic Printing.*
 number. The original which supplies the Copies is a drawing on stone, executed with such materials that when water is poured over the stone it shall not wet the lines of the drawing. When a roller covered with printing ink is passed over the stone, the water prevents it from adhering to the uncovered portions; while the ink used in the drawing is of such a nature that the printing ink adheres to it. In this state, if a sheet of paper be placed upon it, and it is then passed under a press, the printing ink is transferred to the paper, leaving the ink used in the drawing adhering to the stone.

OF COPYING BY CASTING.

The Art of Casting, by pouring substances in a fluid state into a mould which retains them until they become solid, is essentially an Art of Copying. It also happens that the thing produced resembles entirely, as to shape, the pattern from which it was formed.

Of Casting iron and other metals.—Patterns made from drawings are the originals from *Casting metals.*
 which the moulds for Casting are made, so that, in fact, the Casting itself is the Copy of the mould, and the mould is the Copy of the wooden pattern. In castings of iron and metals for the coarser purposes, and, if they are afterwards to be worked, even for the finer machines, the exact resemblance amongst the things produced which takes place in many of the Arts to which we have alluded, does not happen, nor is this necessary. As the metals shrink in cooling, the pattern is made larger than the intended copy; and in extricating it from the sand in which it is moulded, some little difference will occur in the size of the cavity which it leaves.

In smaller work, where accuracy is more requisite, and where few or no after-operations are to be performed, a mould of metal is employed which has been formed with

Manu-
factures.

Sect. I.

considerable care. Thus, in casting bullets, which ought to be perfectly spherical and smooth, an iron instrument is used in which a cavity has been cut and ground with considerable care; and in order to obviate the evil which would otherwise result from the contraction in cooling, a jet is left which may supply the deficiency arising from that cause, and which is afterwards cut off. The leaden toys for children are cast in brass moulds which open, and which have been graved into the figures designed.

Plaster of
Paris.

Casting with plaster.—This is a mode of Copying applied to a variety of purposes;—to produce accurate representations of the human form,—of statues,—or of rare fossils,—to which latter purpose it has lately been applied with great advantage.

In all casting, the first process is to make the mould, and plaster is the substance which is almost always employed in the cases now under consideration. The property which it possesses of remaining for a short time in a state of fluidity, renders it admirably adapted to this purpose, and adhesion is effectually prevented by oiling the surface on which it is poured. The mould formed round the original, removed in separate pieces and then reunited, is that in which the Copy is cast.

Casting in
wax.

Casting in wax.—This mode of Copying, aided by proper colouring, offers the most successful imitations of many objects of Natural History, and gives an air of reality to them which might deceive even the most instructed. Numerous figures of remarkable persons, having the face and hands formed in wax, have been exhibited at various times, and the resemblances have in some instances been most striking. But whoever would see the Art of Copying in wax carried to the highest perfection, should examine the beautiful collection of fruit at the House of the *Horticultural Society*; the model of the magnificent flower of the plant which forms the new genus *Rafflesia*; or the waxen models of the internal parts of the human body which adorn the Anatomical Gallery of the *Jardin des Plantes*, and the *Museum* at Florence.

The Art of imitation by wax does not usually afford the multitude of Copies which flow from many similar operations. This number is checked by the subsequent stages of the process, which, ceasing to have the character of Copying by a tool or pattern, consequently become more expensive. Form alone is given by Casting; the colouring must be the work of the pencil, guided by the artist in each individual production.

OF COPYING BY MOULDING.

This method of producing multitudes of individuals having an exact resemblance in external shape, is adopted very widely in the Arts. The substances employed are either naturally or by artificial preparation, in a soft or plastic state; they are then compressed by mechanical force, sometimes assisted by heat, into a mould of the required form.

Brick-
making.

Of bricks and tiles.—An oblong box of wood fitting upon a bottom fixed to the brick-maker's bench, is the mould from which every brick is formed. A portion of the plastic mixture of which the bricks consist is made ready for the workman by less skilful hands, and being thrown by him with some force into the mould, it fills all the angles. The

*Manu-
factures.* upper surface is then smoothed off by a stick dipped in water drawn across the upper sides of the pattern box. *Sect. I.*

Tiles of various kinds and forms are made of finer materials, but by the same system of Moulding.

Of embossed China.—Many of the forms given to those beautiful specimens of earthen-ware which form the equipage of our breakfast and our dinner tables, are not capable of being executed in the lathe of the potter. The embossed ornaments on the edges of the plates, their polygonal shape, the fluted surface of many of the vases, would all be difficult and costly of execution by the hand; but they become easy and uniform in all their parts, when made by pressing the soft material out of which they are formed, into a hard mould. *Porcelain.*

The care and skill bestowed on the preparation of that mould are repaid by the multitude it produces. In many of the works of the China manufactory one part only of the article is moulded: the upper surface of the plate, for example, whilst the under side is figured by the lathe. In some instances the handle, or only a few ornaments, are moulded, and the body of the work is turned.

Glass seals.—The process of engraving upon gems is one requiring considerable time and skill. The seals thus produced can therefore never become common. Imitations, however, have been made of various degrees of resemblance. The colour which is given to glass is, perhaps, the most successful part of the imitation. A small cylindrical rod of coloured glass is heated in the flame of a blow-pipe, until the extremity becomes soft. The operator then pinches it between the ends of a pair of nippers, which are formed of brass, and on one side of which has been carved in relief the device intended for the seal. When care has been taken in heating the glass properly, and when the mould has been well finished, the seals thus produced are not bad imitations. By this system of Copying they are so multiplied, that at Birmingham the more ordinary kinds are to be purchased at threepence a dozen. *Glass seals.*

Square glass bottles.—The round forms which are usually given to vessels of glass are readily produced by the expansion of the air with which they are blown. It is, however, necessary in many cases to make bottles of a square form, and each capable of holding exactly the same quantity of fluid. It is also frequently desirable to have imprinted on them the name of the maker of the medicine or other liquid they are destined to contain. A mould of iron, or of copper, is provided of the required size, on the inside of which are engraved the names intended. This mould, which is used in a hot state, opens into two parts, to allow the insertion of the round, unfinished bottle, which is placed in it in a very soft state before it is removed from the end of the iron tube with which it was blown. The mould is now closed, and by blowing strongly into the bottle the glass is forced against its sides. *Square glass bottles.*

Wooden snuff-boxes.—Snuff-boxes ornamented with devices, in imitation of carved work or of rose-engine turning, are sold at a price which proves that they are only imitations. The wood, or horn, out of which they are formed, is softened by long boiling in water, and whilst in a soft state it is forced into moulds of iron, or steel, on *Ornamented wooden boxes.*

Manu-
factures.

which are carved or engraved the requisite patterns, where it remains exposed to great pressure until it is dry.

Horn-
working.

Horn knife-handles and umbrella-handles.—The property which horn possesses of becoming soft by the action of water and of heat, fits it for many useful purposes. It is pressed into moulds, and becomes embossed with figures in relief, adapted to the nature and use of the objects to which it is to be applied. If curved, it may be straightened; or if straight, it may be bent into forms which ornament or utility may require; and by the use of the mould these forms may be multiplied in endless variety.

The commoner sorts of knives, the crooked handles for umbrellas, and a multitude of other articles to which horn is applied, attest the cheapness which the Art of Copying gives to the things formed of this material.

Tortoise
shell.

Moulding tortoise shell.—The same principle is applied to things formed out of the shell of the turtle, or the land tortoise. From the greatly superior price of the raw material, this principle of Copying is, however, more rarely employed upon it; and the few carvings which are demanded, are usually performed by hand.

Tobacco
pipes.

Tobacco pipe making.—This simple Art is almost entirely one of Copying. The moulds are formed of iron, and open in the middle; the line of junction of the two parts of the mould may generally be observed running lengthwise from one end of the pipe to the other. The hole passing to the bowl is formed by thrusting a long wire through the clay whilst it is enclosed in the mould. Some of the moulds have figures, or names, sunk in the inside. This gives a corresponding figure in relief upon the finished pipe.

Embossing
calico.

Embossing upon calico.—Calicoes of one colour but embossed all over with various raised patterns, although not much worn in this Country, are in great demand in several foreign markets. This appearance is produced by passing them through a pair of rollers, on one of which is figured in intaglio the pattern to be transferred to the calico. The substance of the cloth is pressed very forcibly into the cavities thus formed, and preserves its figured appearance after considerable use.

Embossing
leather.

Embossing upon leather.—This Art of Copying from steel rollers patterns previously engraved on them, is in most respects similar to the preceding. The leather is forced into the cavities, and that part which is not opposite to any cavity is powerfully condensed between the rollers.

Swaging.

Swaging.—This is an Art of Copying practised by the smith. In order to fashion his iron and steel into the form demanded by his customers, he has small blocks of steel into which are sunk cavities of various shapes; these are called *swages*, and are generally in pairs. If he wants a round bolt, terminating in a cylindrical head of larger diameter, and having one or more projecting rims, he uses a corresponding *swaging* tool; and having heated the end of his iron rod, and thickened it by a process which is technically called *upsetting*, he places its head upon one of the parts; and whilst an assistant holds the other part, he strikes it several times with his hammer, occasionally turning the head one quarter round. The iron which was in a softened state is thus forced by the blows to assume the form of the mould into which it is impressed.

Manu-
factures.

Sect. I.

Transferring
impressions
from steel
to copper.

Engraving copper plates by pressure.—This is one of the most beautiful instances of the Art of Copying carried to an almost unlimited extent; and the delicacy with which it can be executed, and the precision with which the finest traces of the graving tool can be transferred from steel to copper, or even from hard steel to soft steel, is most unexpected. We are indebted to Mr. Perkins for most of the contrivances which have brought this Art at once almost to perfection. An engraving is first made upon soft steel, which is hardened by a peculiar process without in the least injuring its delicacy. A cylinder of soft steel, pressed with great force against the hardened steel engraving, is now made to roll slowly backward and forward over it. The soft steel cylinder receives the design, but it is in relief. This is in its turn hardened without injury; and if it be slowly rolled to and fro with strong pressure on successive plates of copper, it will imprint on a thousand of them a perfect fac-simile of the original steel engraving from which it resulted. Thus is the number of copies producible from the same design multiplied a thousand fold.

But even this is very far short of the limits to which this process may be extended. The hardened steel roller may be employed to make a few of its first impressions upon plates of *soft steel*, and these being hardened may in their turn become the parents of other rollers, each generating copper plates like the original. The possible extent to which fac-similes of an original engraving may thus be multiplied, almost confounds the imagination, and appears to be, for all practical purposes, unlimited. There are two principles which peculiarly fit this Art for rendering the forgery of Bank-notes, to prevent which Mr. Perkins proposed it, a matter of great difficulty. The first is the perfect identity of every impression with every other, so that any variation in the minutest line would at once cause detection. The other principle is, that the plates from which all the impressions are deduced may be formed by the united labours of artists most eminent in their several departments, all working at the same time; and that, as only one original of each design is necessary, the expense, however great, will be trifling, compared with the immense multitude of copies produced from it.

Gold and silver moulding.—Many of the mouldings used by jewellers consist of thin slips of metal, which have received their form by passing between steel rollers, thus taking a succession of Copies of the devices engraved upon them.

Ornamental papers.—Sheets of paper coloured or covered with gold or silver leaf, and embossed with various patterns, are used for covering books, and for many ornamental purposes. The figures upon these are produced by the same process, that of passing the sheets of paper between engraved rollers.

Embossing
ornamental
paper.

OF COPYING BY STAMPING.

This principle of Copying is extensively employed in the Arts. It is generally executed by means of large presses worked with a screw and heavy fly-wheel. The

Manu-
factures.

materials on which the Copies are impressed are most frequently metals, and the process is sometimes executed when they are hot, and in one case when the metal is in a state between solidity and fluidity.

Sect. I.

Coining.

The whole of the coins which circulate as money are produced by this mode of Copying. The screw-presses are either worked by manual labour, or by water, or steam power. The Mint which was sent a few years since to Calcutta was capable of coining 200,000 pieces a day.

Medals, which usually have their figures in higher relief than coins, are produced by similar means; but a single blow is rarely sufficient to bring them to perfection, and the compression of the metal which arises from the first blow renders it too hard to receive many subsequent blows without injury to the die. It is therefore, after being struck, removed to a furnace in which it is carefully heated red-hot and annealed, after which operation it is again placed between the dies, and receives additional blows. For large medals, and those on which the figures are very prominent, these processes must be repeated many times. One of the largest medals hitherto struck underwent them nearly one hundred times before it was completed.

Ornaments on military accoutrements and furniture ornaments.—These are usually made of brass, and are stamped up out of solid or sheet brass by placing it between dies, and allowing a heavy weight to drop upon the upper die from a height of from five to fifteen feet.

Buttons.

Buttons and nail-heads.—Buttons embossed with crests or other devices are produced by the same means, and some of those which are plain receive their hemispherical form from the dies in which they are struck.

The heads of several kinds of nails which are portions of spheres, or polyhedrons, are also formed by these means.

Clichée.

Of a process for Copying, called, in France, Clichée.—This curious method of Copying by stamping is applied to medals, and in some cases to forming stereotype plates. There exists a range of temperature previous to the melting point of several of the alloys of lead, tin, and antimony, in which the compound is neither solid, nor yet fluid. In this kind of pasty state it is placed in a box under a die, which descends upon it with considerable force. The blow drives the metal into the finest lines of the die, and the coldness of the latter immediately solidifies the whole mass. A quantity of the half melted metal is driven about by the blow in all directions, and is retained by the sides of the box in which the process is carried on. The work thus produced is admirable for its sharpness; but it has not the finished form of a piece just leaving the coining press. The sides are ragged, and it must be trimmed, and its thickness equalized in the lathe.

OF COPYING BY PUNCHING.

This mode of Copying consists in driving, either by a blow or by pressure, a steel punch through the substance to be cut. In some cases the object is to make repeated

Manu-
factures.

Copies of the same sized aperture, and the substance separated from the plate is rejected: in other cases it is the small pieces cut out which are the objects of the workman's labour.

Sect. I.

Punching iron plate for boilers.—The steel punch used for this purpose is from three-eighths to three-quarters of an inch in diameter, and drives out from a plate of iron a circular disc from one-quarter to five-eighths of an inch thick. Punching.

Punching tinned iron.—The ornamental patterns of open work which decorate the tinned and japanned wares in general use, are rarely punched by the workman who makes them. In London the Art of punching out these patterns in screw-presses is carried on as a separate trade, and large quantities of sheet tin are perforated for cullenders, wine-strainers, borders of waiters, and other similar purposes. The perfection and the regularity to which the Art has been carried are considerable: sheets of copper too are punched with small holes about the hundredth of an inch in diameter, in such multitudes that more of the sheet of metal is removed than remains behind, and plates of tin have been perforated with above three thousand holes in each square inch. Punching
tinned iron.

In all the remaining illustrations of the Art of Copying by punching, the part made use of is that which is punched out.

Cards for guns.—The substitution of a circular disc of thin card instead of paper for retaining in its place the charge of a fowling piece, is attended with considerable advantage. It would, however, be of little avail, unless an easy method was contrived of producing an unlimited number of cards, each exactly fitting the bore of the barrel. The small steel tool used for this purpose cuts out innumerable circles similar to its cutting end, each of which precisely fills the barrel for which it was designed. Cards for
wadding.

Ornaments of gilt paper.—The golden stars, leaves, and other devices, sold in shops for the purpose of ornamenting articles made of paper and pasteboard, and other fancy works, are cut by punches of various forms out of sheets of gilt paper. Paper orna-
ments.

Steel chains.—The chain used in connecting the main spring and fusee in watches and clocks, is composed of small pieces of sheet steel. It is of great importance that each of these pieces should be of exactly the same size. The links are of two sorts; one of them consisting of a single oblong piece of steel with two holes in it, and the other formed by connecting two of the same pieces of steel, placed parallel to each other at a short distance, by two rivets. These two kinds of links occur alternately, and the single piece, which forms one of them, has each end placed between the ends of the adjacent double pieces, with which it is connected by the rivets which pass through all three. If the double pieces had the holes for the rivets placed at unequal distances the chain would not be straight, and would, consequently, be unfit for its purpose. Steel
chains.

COPYING WITH ELONGATION.

In this species of Copying there exists but little resemblance. It is the cross section of the thing produced which is similar to the tool through which it passes. When

Manu-
factures.

the substances to be operated upon are hard, they frequently pass in succession through several holes, and it is in some cases necessary to anneal them at intervals.

Wire-
drawing.

Wire-drawing.—The metal to be converted into wire is made of a cylindrical form, and drawn forcibly through circular holes in plates of steel; at each passage it becomes smaller, and when finished its section at any point is a precise copy of the last hole through which it passed. Upon the larger kinds of wire fine lines may frequently be traced running longitudinally: these arise from a slight imperfection in the holes of the draw-plates.

For many purposes of the Arts, wire, the section of which is square or half round, is required: the same method of making it is pursued, except that the holes through which it is drawn are in such cases themselves square, or half round, or of whatever other form the wire is required to be.

A species of wire is made, the section of which resembles a star with from six to twelve rays, this is called pinion wire, and is used by the clock-makers. They file away all the rays from a short piece, except from about half an inch near one end: this becomes a pinion for a clock, and the leaves having passed through the draw-plate are already burnished and finished.

Tube
drawing.

Tube drawing.—The Art of forming tubes of uniform diameter is nearly similar in its mode of execution to wire-drawing. After the sheet-brass has been bent round and soldered, if the outside diameter is that which is required to be uniform, it is drawn through a succession of holes, as in wire-drawing. If the inside diameter is to be uniform, a succession of steel cylinders, called *triblets*, are drawn through the brass tube.

In making tubes for telescopes it is necessary that both the inside and outside should be uniform. A steel *triblet* is passed into the tube, which is then drawn through a succession of holes, until the outside diameter is reduced to the required size. The metal of which the tube is formed, is condensed between the holes and the steel cylinder within it; and when the latter is withdrawn the internal surface appears polished. The brass tube is considerably extended by this process, sometimes even to double its first length.

Leaden
pipes.

Leaden pipes for the conveyance of water were formerly made by casting; but it has been found that they can be made both cheaper and better by drawing them through holes in the manner of wire. A cylinder of lead of five or six inches in diameter, and about two feet long, is cast with a small hole through its axis, and an iron *triblet* fifteen feet in length is forced into the hole. It is then drawn through a series of holes until the lead has extended from one end to the other of the *triblet*, and is of the proper thickness in proportion to the size of the pipe.

Iron rolling.—When cylinders of iron, of greater thickness than wire, are required, they are formed by passing wrought iron between rollers each of which has sunk in it a semicylindrical groove; and as such rollers rarely touch accurately in iron so manufactured, a longitudinal line will usually be observed. Bar iron is manufactured in this way into all the various shapes of round, square, half-round, oval, &c. in which it occurs

<sup>Manu-
factures.</sup> in commerce. It is sometimes required that the iron thus produced shall not be of ^{Sect. I.} uniform thickness throughout. This is the case in rolling iron for rail-roads, for which <sup>Iron
rail-roads.</sup> purpose greater depth is required towards the middle of the rail which is at the greatest distance from the supports. This is accomplished by cutting the groove in the rollers deeper at those parts wherein additional strength is required; so that the hollow which surrounds the roller would, if it could be unwound, be a mould of the shape the iron is intended to fit.

Vermicelli.—The various forms into which this paste is made are given by forcing ^{Pastry} it through holes in tin plate. It passes through them, and appears on the other side in long strings. The cook and the confectioner make use of the same method; the former in preparing butter and ornamental pastry for the table, the latter in forming the cylindrical lozenges of various composition.

OF COPYING WITH ALTERED DIMENSIONS.

Of the pentagraph.—This mode of Copying is chiefly used for Drawings or Maps: the instrument is simple, and, although usually employed in reducing, is capable of increasing the size of the Copy produced.

An automaton figure, which drew profiles of its visitors, and which was exhibited in London a short time since, was regulated by a mechanism on this principle. <sup>Automaton
Profile
drawer.</sup>

A small aperture in the wall, opposite the seat in which the person is placed whose Profile is taken, conceals a *camera lucida*. If an assistant moves the point, connected by a pentagraph with the hand of the automaton, over the outline of the head, a corresponding profile is traced by the figure.

Rose engine turning.—This elegant Art depends in a great measure on Copying. The rosettes which are placed on the mandril oblige the cutting tool to trace out the same <sup>Engine
turning.</sup> pattern on the work, and the distance of the tool from the centre being usually less than the radius of the rosette, causes the copy to be much diminished.

Copying dies.—A lathe has been long known in France, and recently been used at the English Mint for copying dies. A blunt point is carried by a very slow spiral movement successively over every part of the die to be copied, and is pressed by a weight into all the cavities; while a cutting point connected with it by the machine traverses the face of a piece of soft steel, in which it cuts on the same or on a diminished scale, the device on the original die. The degree of excellence of the copy increases in proportion as it is smaller than the original. The die of a crown piece will furnish by copy a very tolerable die for a sixpence. But the chief use to be expected from this lathe is to prepare all the coarser parts, and leave only the finer and more expressive lines for the skill and genius of the artist. ^{Die copying}

An instrument not very dissimilar in principle to this was proposed for the purpose of making shoe lasts. A pattern last of a shoe for the right foot was placed in one part of the apparatus; and, when the machine was moved, two pieces of wood, placed in <sup>Shoe last
making.</sup>

Manu-
factures.

another part which had been previously adjusted by screws, were cut into lasts greater or less than the original, as was desired; and although the pattern was for the right foot one of the lasts was for the left.

Screw
cutting.

Screw cutting.—When this operation is performed in the lathe by means of a screw upon the mandril, it is essentially an Art of Copying, but it is only the number of threads in a given length which is Copied; the form of the teeth, and length as well as the diameter of the screw to be cut, are entirely independent of those from which the Copy is made. There is another method of cutting screws in a lathe by means of one pattern screw, which, being connected by wheels with the mandril, guides the cutting point. In this process, unless the time of revolution of the mandril is the same as that of the screw which guides the cutting point, the number of threads in a given length will be different. If the mandril move quickest, the screw which is produced will be finer than the original; if it move slower, the Copy will be more coarse than the original. The screw thus generated may be finer or coarser,—it may be larger or smaller in diameter,—it may have the same number of threads or a greater number than that from which it is Copied; yet all the defects which exist in the original will be accurately transmitted, under the modified circumstances, to every individual generated from it.

The Art of turning might perhaps itself be classed amongst the Arts of Copying. All work which is executed on a mandril partakes in some measure of the irregularities of that mandril, and the perfect circularity of section which ought to exist at every part, can only be ensured by an equal accuracy in the mandril and its collar.

Impressions
of various
size from the
same copper
plate.

Some very singular specimens of an Art of Copying, not yet made public, were brought from Paris a few years since. A watch-maker in that city, of the name of Gonord, had contrived a method by which he could take from the same copper plate impressions of different sizes, either larger or smaller than the original design. Four impressions of an Eagle were examined in the presence of the writer of this paper, by a late artist equally distinguished for his skill and for the many mechanical contrivances with which he enriched his Art. The largest was four times the superficial size of the smallest, and no lines were detected in one which had not corresponding lines in the others. There appeared to be a difference in the quantity of ink, but none in the traces of the engraving. The processes by which this singular operation was executed have not been published, but two conjectures were formed at the time which merit notice. It was supposed that the artist was in possession of some method of transferring the ink from the lines of a copper plate to the surface of some viscous fluid, and also of retransferring the impression from the fluid to paper. If this could be accomplished, the Print would be of exactly the same size as the copper from which it was derived; but if the viscous fluid were contained in a vessel having the form of an inverted cone with a small aperture at the bottom, the liquid might be lowered or raised in the vessel by gradual abstraction or addition through the apex of the cone; in this case, the surface to which the printing ink adhered would diminish or enlarge, and in this altered state the impression might be retransferred to paper. It must be admitted, that this conjectural expla-

Explanation

Manu-
factures.

Sect. I.

nation is not without considerable difficulties, for although the converse operation of taking an impression from a liquid surface has a parallel in the Art of marbling paper, the possibility of transferring the ink from the copper to the fluid requires to be proved.

Another and more plausible explanation is founded on the elastic nature of the compound of glue and treacle, a substance already in use in transferring engravings to earthenware. It is conjectured, that an impression from the copper plate is taken upon a large sheet of this composition; that this sheet is then stretched in both directions, and that the ink thus expanded is transferred to paper. If the Copy is required to be smaller than the original, the elastic substance must first be stretched, and then receive the impression from the copper plate: on removing the tension it will contract, and thus reduce the size of the design. It is possible that one transfer may not in all cases suffice, as the extensibility of the composition of glue and treacle, although considerable, is still limited.

Second
explanation.

Perhaps sheets of Indian rubber of uniform texture and thickness may be found to answer better than this composition. As it would require considerable time to produce impressions in this manner, and there might arise some difficulty in making them all of precisely the same size, the process might be rendered more certain and expeditious, by performing that part of the operation which depends on the enlargement or diminution of the design only once; and, instead of printing from the soft substance, transferring the design from it to stone: thus a considerable portion of the work would be reduced to an Art already well known, that of Lithography.

We shall terminate this enumeration, which is far from complete, of the Arts in which Copying is the foundation, with an example which has long been under the eye of our readers, although few, perhaps, are aware of the great extent of repeated Copying of which these very pages are the subject.

Instance
of multi-
plied
Copying.

1. They are Copied by Printing from stereotype plates.
2. These stereotype plates are Copied, by the Art of casting, from moulds formed of plaster of Paris.
3. Those moulds are themselves Copied by casting the plaster in a liquid state upon the movable type set up by the compositor.

[It is here that the union of the intellectual and the mechanical departments takes place. Through how many stages of repeated Copying the matter which is here delivered to the reader may have travelled, we shall leave involved in a veil which his sagacity may penetrate; merely observing, that in numerous instances the mental far outruns the mechanical Copyist.]

4. These movable types, the obedient messengers of the most opposite thoughts, the most conflicting theories, are themselves Copies, by casting from moulds of copper called *matrices*.

5. The lower part of those *matrices* bearing the impressions of the letter or character intended, are Copies by punching from steel punches on which the same character exists in relief.

Manu-
factures.

Sect. I.

6. These steel punches are not themselves entirely exempted from the great principle of Art. Many of the cavities which exist in them, such as those in the middle of the punches for the letters *a, b, d, e, g, &c.* are produced from other steel punches in which these parts are in relief.

We have thus traced through six successive stages of Copying the mechanical Art of Printing from stereotype plates. In this, as in every other department of Manufacture, the principle of Copying contributes to the uniformity and the cheapness of the work produced.

CHAPTER II.

OF THE ECONOMICAL PRINCIPLES OF MANUFACTURES.

INTRODUCTION.

*Manu-
factures.* To produce any article of consumption in a perfect form is the first object of every person who attempts to make it; but in order to secure to himself the greatest and most permanent profit, he must endeavour by every means in his power to render the new luxury or want, which he has created, cheap to those who consume it.

The number of his purchasers will, in some measure, secure him from the caprices of fashion, whilst it furnishes a far larger amount of profit, although the contribution of each individual is diminished.

If, therefore, he wish to become a Manufacturer, he must attend to other principles besides those mechanical ones on which the successful execution of his work depends; he must carefully arrange the whole system of his factory in such a manner, that the article he sells to the Public may be produced at as small cost as possible.

Should he not be actuated by such remote motives, he will in every highly civilized Country be compelled, by the powerful stimulus of competition, to attend to these principles of the domestic economy of Manufactures. At every reduction in price of the commodity he makes, he will be driven to seek compensation in a saving of expense in some of the processes, and his ingenuity will be sharpened in this inquiry by the hope of being able in his turn to undersell his rivals.

The improvements thus engendered remain for a short time enriching those from whose ingenuity they derived their origin; but when a sufficient experience has shown their value, they become generally adopted, until these in their turn are superseded by other more economical methods.

The *economical principles* which regulate the application of Machinery, and which govern the interior of all our great factories, are quite as essential to the prosperity of a great commercial Country, as are those Mechanical ones the operations of which we have attempted to illustrate in the preceding Chapter.

ON THE DIVISION OF LABOUR.

One and perhaps the most important principle on which the economy of a Manufacture depends, is the division of labour amongst the operatives who work at it. The first application of this principle must have been made in a very early stage of Society, and it must soon have been apparent, that more comforts and conveniences could be acquired by one man restricting his occupation to the art of making bows, another to that of building houses, a third boats, and so on.

This division of labour into Trades was not, however, the result of an opinion, that the <sup>Division of
labour.</sup> general riches of the community would be increased by such an arrangement; but it

Manu-
factures.

arose from the circumstance of each individual so employed discovering that he himself could thus make a greater profit of his labour than by pursuing more varied occupations.

Sect. 1.

Society must have made considerable advances before that principle could have been carried into the workshop, for it is only in Countries which have attained a high degree of civilization, and in articles in which there is a great competition amongst the producers, that the most perfect system of the division of labour is to be observed.

The principles on which the advantages of this system depend, have been much the subject of discussion amongst writers on Political Economy, but the relative importance of their influence does not appear in all cases to have been estimated with sufficient precision.

It is our intention in the first instance to state shortly those principles, and then to point out the omissions which have been made by those who have treated the subject, and more especially by one of our own authors of the highest authority.

Time con-
sumed in
learning.

1. Of the time required for learning.

It will readily be admitted, that the portion of time occupied in the acquisition of any Art will depend on the difficulty of its execution, and that the greater the number of distinct processes, the longer will be the time which the apprentice must employ in acquiring it. Five or seven years have been adopted in a great many trades as the time considered requisite for a lad to acquire a sufficient knowledge of an Art, and to repay by his labour, during the latter portion of his time, the expense incurred by his master at its commencement. If, however, instead of learning all the several processes of making a needle, for instance, his attention is confined to one operation, a very small portion of his time will be consumed unprofitably at the commencement, and the whole of the rest of it will be beneficial to his master; and if there be any competition amongst the masters, the apprentice will be able to make better terms and diminish the period of his servitude. Again, the facility of acquiring skill in a single process, and the early period of life at which it can be made a source of profit, will induce a greater number of parents to bring up their children to it; and from this circumstance also, the number of workmen being increased, the wages will soon fall.

Material de-
stroyed in
learning.

A certain quantity of material will be consumed unprofitably or spoiled by every person who learns an Art, and as he applies himself to each new process, he will waste a certain quantity of the raw material, or of the partly manufactured commodity. But whether one man in succession commits this waste in acquiring each process, or many persons separately learn the several processes, the quantity of waste will remain the same; therefore in this view of the subject the division of labour will neither increase nor diminish the price of production.

Loss of time
in changing
occupation.

2. Another reason of the advantage resulting from the division of labour is, that *time is always lost in changing from one occupation to another.*

When the human hand or the human head has been for some time occupied in any kind of work, it cannot instantly change its employment with full effect. The muscles of the limbs employed have acquired a flexibility during their exertion, and those to be put in action a stiffness during rest, which renders any change in the commencement

^{Manu-}slow and unequal. A similar result seems to take place in any change of mental ex-
^{factures.}ertion; the attention bestowed on the new subject is not so perfect at the first com-
 mencement as it becomes after some exercise. Long habit also produces in the muscles
 exercised a capacity for enduring fatigue to a much greater degree than they could
 support under other circumstances.

Sect. I.

Another cause of the loss of time in changing from one operation to another, arises
 from the employment of different tools in the two processes. If these tools are simple
 in their nature, and the change is not frequently repeated, the loss of time is not con-
 siderable; but in many processes of the Arts there are tools of great delicacy, requiring
 accurate adjustment whenever they are used. In many cases the time employed in
 adjusting bears a large proportion to that employed in using the tool. The sliding
 rest, the dividing and the drilling engine, are of this kind, and hence in Manufactories
 of sufficient extent, it is found to be good economy to keep one Machine constantly
 employed in one kind of work; one lathe, for example, having a screw motion to its
 sliding rest along the whole length of its bed, is kept constantly making cylinders;
 another, having a motion for rendering uniform the velocity of the work at the point
 at which it passes the tool, is kept for facing surfaces; whilst a third is constantly
 employed in cutting wheels.

In adjust-
ment of
tools.

3. Skill acquired by frequent repetition of the same processes.

The constant repetition of the same process necessarily produces in the workman a
 degree of excellence and rapidity in his particular department, which is never possessed
 by one who is obliged himself to execute many different processes. This rapidity is
 still further increased from the circumstance of most of the operations in factories, where
 the division of labour is carried to a considerable extent, being paid for as piece-work.
 It is difficult to estimate the numerical effect of this cause upon production. In nail-
 making, Adam Smith has stated that it is almost three to one; or, in other words, that
 a smith accustomed to make nails, but whose whole business has not been that of a
 nailer, can make only from eight hundred to a thousand per day; whilst a lad who had
 never exercised any other trade, can make upwards of two thousand three hundred a day.

Skill ac-
quired by
repetition.

In different trades the economy of production arising from this cause will neces-
 sarily be different. The case of nail-making is perhaps rather an extreme one. It
 must, however, be observed that in one sense, this is not a permanent cause, for although
 it acts at the commencement of an establishment, yet every month adds to the skill of
 the workman, and at the end of a certain time he will not be very far behind those
 who have practised only the peculiar branch.

4. The division of labour suggests contrivances for tools and Machinery to execute its processes.

Suggests
tools.

When each process by which any article is produced is the sole occupation of one
 individual, his whole attention being devoted to a very limited and simple operation, any
 improvement in the form of his tools, or in the mode of using them, is much more likely
 to occur to his mind, than if it were distracted by a greater variety of circumstances. Such
 an improvement in the tool is generally the first step towards a Machine. If a piece of

Manu-
factures.

metal is to be cut in a lathe, for example, there is one angle at which the cutting tool must be held to ensure the cleanest cut ; it is quite natural that the idea of fixing the tool at that angle should present itself to an intelligent workman. The necessity of moving the tool slowly, and in a direction parallel to itself, would suggest the use of a screw, and thus arises the sliding rest. It was probably the idea of mounting a chisel in a frame, to prevent its cutting too deeply, which gave rise to the common carpenter's plane. In other instances a blow from a hammer is employed, and experience teaches the proper force required. The transition from the hammer held in the hand to one mounted upon an axis, and lifted regularly to a certain height by the foot, requires perhaps a greater degree of invention. Yet it is not difficult to perceive that if the hammer always falls from the same height its effect must be always the same.

Sect. I.

Union of
tools makes
masses.

When each process has been reduced to the use of some simple tool, the union of all these actuated by one moving power constitutes a Machine. In contriving tools and processes, the operative workmen are perhaps most successful, but it requires far other habits to combine into one Machine these scattered Arts. A previous education as a workman in the peculiar Trade is undoubtedly a valuable preliminary, but to do it with any reasonable expectation of success, an extensive knowledge of Machinery, and the power of making mechanical drawings are essentially requisite. Such accomplishments are now much more frequent than they were formerly, and their absence was perhaps one of the causes of the multitude of failures in the early history of many of our Manufactures.

Such are the principles usually assigned as the cause of the advantages resulting from the division of labour. As in our view of the question a very prominent cause has been altogether unnoticed, we shall give them in the words of Adam Smith.

“ The great increase in the quantity of work which in consequence of the division of labour the same number of people are capable of performing, is owing to three different circumstances : first, to the increase of dexterity in every particular workman ; secondly, to the saving of time, which is commonly lost in passing from one species of work to another ; and, lastly, to the invention of a great number of Machines which facilitate and abridge labour, and enable one man to do the work of many.”

Now although these causes are all important ones, and have each their influence in the result, yet it appears to us that any explanation of the cheapness of Manufactured articles as resulting from the division of labour, would be incomplete if the following principle were omitted to be stated.

Division of
labour en-
ables mas-
ters to pur-
chase pre-
cisely that
portion of
skill re-
quired.

That the master Manufacturer, by dividing the work to be executed into different processes, each requiring different degrees of skill and of force, can purchase exactly that precise quantity which is necessary for each process ; whereas, if the whole work were executed by one workman, it is evident that that workman must possess sufficient skill to perform the*

* The writer of this Essay derived his first knowledge of this principle from a personal examination of a variety of Manufactories and Workshops devoted to different purposes ; but he has since found that it has been distinctly stated in the Work of Gioja, *Nuovo Prospetto delle Scienze Economiche*, 6 tom. 4to. Milano, 1815, tom. i. capo iv.

Manu- *most difficult, and sufficient strength to execute the most laborious, of the operations into which* Sect. I.
factures. *the Art is divided.*

As the clear apprehension of this principle, upon which so much of the economy arising from the division of labour depends, is of considerable importance, it may be desirable to illustrate it by pointing out its precise and numerical application in some specific Manufacture. The art of making needles is perhaps that which we should have selected as comprehending a very large number of processes remarkably different in their nature; but the less difficult art of pin-making, referred to by Adam Smith, has some claim to our attention from its having been used as the earliest illustration of the subject; and we are confirmed in the choice by the circumstance of possessing a very accurate and minute description of that Art as practised in France above half a century ago.

In the Manufacture of pins in England the following processes are employed.

1. The brass wire used for making pins is purchased by the Manufacturer in coils of about twenty-two inches in diameter, each weighing about thirty-six pounds. These coils are wound off into smaller ones of about six inches diameter, and between one and two pounds weight. Example.
Pinmaking.

The diameter of this wire is now reduced by drawing it repeatedly through holes in steel plates until it becomes of the size required for the sort of pins intended to be made; during the process of drawing the wire through these holes it becomes hardened, and it is necessary to anneal it in order to prevent its breaking, and to enable it to be still further reduced; it is annealed two or three times according to the diminution of diameter required.

These coils are soaked in sulphuric acid largely diluted with water, in order to clean them, and are then beaten on stone, for the purpose of removing any oxidated coating which may adhere to them.

This process is usually performed by men, who draw and clean from thirty to thirty-six pounds a day. They are paid at the rate of five farthings per pound, and generally earn about 3s. 6d. per day.

M. Perronet made some experiments on the extension of the wire at each hole. He took a piece of Swedish brass wire, and found

	Feet.	Inches.
Its length to be	3	8
After passing the first hole	5	5
———— second hole	7	2
———— third hole	7	8
It was now annealed, and		
After passing the fourth hole	10	8
———— fifth hole	13	1
———— sixth hole	16	8
And after passing through six others	144	0

The holes through which the wire was drawn were not in this experiment of regularly decreasing diameter; and it is extremely difficult to make such holes, and still more to preserve them in their original dimensions.

2. The coil of wire now passes into the hands of a woman, assisted by a boy or girl.

Manu-
factures.
Straighten-
ing the wire.

A few nails, not quite in a line, are fixed into one end of a wooden table; the end of the wire is passed alternately between these nails, and is then pulled to the other end of the table about twenty feet in length. The object of this process is to straighten the wire which had acquired an uniform curvature in the small coils into which it had been wound. The length thus straightened is cut off, and the remainder of the coil is drawn into similar lengths. Sect. I.

About seven nails or pins are employed in straightening the wire, and the adjustment is a matter of some nicety. It seems, that by passing the wire between the first three nails or pins a bend is produced in an opposite direction to that which the wire had in the coil; this bend is again reduced to another of larger curvature in the first direction, and so on until the curvature of the last is so large that it may be confounded with a straight line.

A man next takes a parcel, about 300 of these pieces, and putting them into a gauge cuts off from one end, by means of a pair of shears moved by his foot, about 300 pieces, each equal in length to rather more than six pins. He continues this operation until the whole parcel is reduced into similar pieces.

Sharpening
points.

The next step is to sharpen the ends of these pieces: for this purpose the operator sits before a steel mill, which is kept rapidly revolving; and taking up a parcel between the finger and thumb of each hand, he passes the ends before the mill, taking care with his fingers and thumbs to make each wire slowly revolve. The mill consists of a cylinder about six inches in diameter, and two and a half inches broad, faced with steel, which is cut in the manner of a file. Another similar one is fixed on the same axis at a few inches distant; the file on the edge of this is of a finer kind, and is used for finishing off the points. Having thus pointed all the pieces at one end he reverses them, and performs the same process upon the other ends. This process requires considerable skill, but it is not unhealthy; whilst the similar process in needle-making is remarkably destructive of health.

These pieces, which are now pointed at both ends, are placed in gauges, and the pointed ends are cut off by means of shears to the proper length of which the pins are to be made. They are now equal to about four pins in length, and are again pointed at each end, and their ends again cut off. This process is repeated a third time, and the small portion of wire in the middle is thrown amongst the waste, to be melted up with the dust arising from the sharpening.

It is usual for a man, his wife, and a child, to join in performing these processes; and they are paid at the rate of five farthings per pound. They can do from thirty-four to thirty-six and a half pounds per day, and gain from 6s. 6d. to 7s., which may be apportioned thus; 5s. 6d. the man, 1s the woman, 6d. to the boy or girl.

Making the
heads.

3. The next process is making the heads. For this purpose a boy takes a piece of wire, of the same diameter as the pin to be headed, which he fixes on an axis that can be made to revolve rapidly by means of a wheel and strap connected with it. This wire is called the mould. He then takes a smaller wire, which having passed through an eye in a small tool held in his left hand, he fixes close to the bottom of the mould. The

Manu-
factures.

Sect. I.

mould is now made to revolve rapidly by means of the right hand, and the smaller wire coils round it until it has covered the whole length of the mould. The boy now cuts the end of the spiral connected with the foot of the mould, and draws it off.

When a quantity of heading is thus made, a man takes from thirteen to twenty of these spirals in his left hand between his thumb and three outer fingers; these he places in such a manner that two turns of the spiral shall be beyond the upper edge of a pair of shears, and with the fore finger of the same hand he feels these two projecting turns. With his right hand he closes the shears, and the two turns of the spiral being cut off drop into a basin. The position of the fore finger prevents the heads from flying about when cut off.

The workmen who cut the heads are usually paid at the rate of $2\frac{1}{4}d.$ to $3d.$ per pound for large, but a higher price is given for the smaller heading. Out of this they pay the boy who spins the spiral; he receives from $4d.$ to $6d.$ per day. A good workman can cut from 6 pounds to about 30 pounds of heading per day, according to its size.

4. The process of fixing on the head to the body of the pin is usually executed by women and children. Each operator sits before a small steel stake, having a cavity, into which one-half of the intended head will fit; immediately above is a steel die, having a corresponding cavity for the other half of the head: this latter die can be raised by a pedal moved by the foot. The cavities in the centre of these dies are connected with the edge by a small groove, to admit of the body of the pin, which is thus prevented from being flattened by the blow of the die. The operator with his left hand dips the pointed end of the body of a pin into a tray of heads, and having passed the point through one of them, he carries it along to the other end with the fore finger. He now takes the pin in the right hand, and places the head in the cavity of the stake, and lifting the die with his foot allows it to fall on the head. This blow tightens the head on the shank, which is then turned round, and the head receives three or four blows on different parts of its circumference. The women and children who fix the heads are paid at the rate of $1s. 6d.$ for every 20,000. A skilful operator can with great exertion do 20,000 per day, but from 10,000 to 15,000 is the usual quantity: children head a much smaller, number varying of course with the degree of their skill.

Fixing the
heads.

The weight of the hammer is from seven to ten pounds, and it falls through a very small space, perhaps from one to two inches. About one per cent. are spoiled in the process; these are picked out afterwards by women, and are reserved with the waste from other processes for the melting pot. The form of the dies in which the heads are struck is varied according to the fashion of the time, but the repeated blows to which it is subject renders it necessary that it should be repaired after it has been used for about thirty pounds of pins.

5. The pins are now fit to be tinned, a process which is usually executed by a man assisted by his wife, or by a lad.

Tinning the
pins.

The quantity of pins operated upon at this stage is usually fifty-six pounds. They are first placed in a pickle in order to remove any grease or dirt from their surface, and also to render that surface rough, which facilitates the adherence of the tin with which they

Manu-
factures.

are to be covered. They are then placed in a boiler full of a solution of tartar in water in which they are mixed with a quantity of tin in small grains. They are usually kept boiling for about two hours and a half, and are then removed into a tub of water into which some bran has been thrown; this is for the purpose of washing them. They are then taken out, and being placed in wooden trays are well shaken in dry bran; this removes any water adhering to them, and by giving the wooden tray a peculiar kind of motion, the pins are thrown up, and the bran gradually flies off, and leaves them behind in the tray.

Sect. I.

The man who pickles and tins the pins usually gets one penny per pound for the work, and employs himself during the boiling of one batch of pins with drying those previously tinned. He can earn about 9s. per day; but out of this he pays about three for his assistant.

Papering
the pins.

6. The arranging of pins side by side in paper is generally performed by women. The pins come from the last process in wooden bowls, with the points projecting in all directions. A woman takes up some and places them on the teeth of a comb, whilst, by a few shakes, some of the pins fall back into the bowl, and the rest, being caught by their heads, are detained between the teeth of the comb. Having thus arranged them in a parallel direction, she fixes the requisite number between two pieces of iron, having twenty-five small grooves, at equal distances, and having previously doubled the paper, she presses it against the points of the pins until they have passed through the two folds which detain them. The pins are then relieved from the tool, and the process repeated. A woman gains about 1s. 6d. per day by papering, but children are sometimes employed, who earn from 6d. per day, and upwards.

Having thus described the various processes without entering into the minuter details, and having stated the usual cost of each, it will be convenient to present a Tabular view of the time occupied by each process, and its cost, as well as of the sums which can be earned by the operative who devotes himself solely to each process. As the rate of wages is itself fluctuating, and as the prices paid and quantities executed have been given between certain limits, it is not to be expected that this Table can represent with the minutest accuracy the cost of each part, nor even that it shall accord perfectly with the prices above given; but it has been drawn up with some care, and will be quite sufficient for that general view and for those reasonings which it is meant to illustrate. We shall annex a Table nearly similar, which we have deduced from statements of M. Perronet, respecting the Art of pin-making in France above seventy years ago.

* The expense of turning the wheel appears to have arisen from the person so occupied being sufficiently employed only half his time, whilst the pointer went to another manufactory.

Manu-
factures.

From an examination of the first of these Tables it appears that the wages earned by the operatives vary from $4\frac{1}{2}d.$ per day up to $6s.$, and consequently the skill which is required for their respective employments will be measured by those sums. Now it is evident that if one person is required to make the whole pound of pins, he must have skill enough to earn about $5s. 3d.$ a day whilst he is pointing or cutting off the heads, and $6s.$ when he is whitening the pins; which three operations together would occupy little more than the seventeenth part of his time. It is also apparent, that during more than one-half of his time he must be earning only $1s. 3d.$ per day in putting on the heads, although his skill, if properly employed, would, in the same time, produce nearly five times as much.

Sect. I.

It appears from the analysis we have given of the Art of pin-making, that it occupies rather more than seven hours and a half of time for ten different individuals working in succession on the same material to convert it into a pound of pins, and that the expense of their labour, each being paid in the joint ratio of his skill and the time he is employed, amounts to nearly $1s. 1d.$ Now if we were to employ the man who whitens the pins, and who earns $6s.$ a day, even supposing that he could make the pound of pins in an equally short time, yet we must pay him for his time 46.14 pence, or nearly $3s. 10d.$ *The pins would therefore cost in making three times and three quarters as much as they now do by the application of the division of labour.*

The higher the skill required of the workman in any one process of a Manufacture, and the smaller the time during which it is employed, so much the greater will be the advantage of separating that process from the rest and devoting one person's attention entirely to it. Had we selected the Art of needle-making as our illustration, the economy arising from the division of labour would have been still larger, for the process of tempering the needles requires great skill, attention, and experience, and although from three to four thousand are tempered at once, the workman is paid a very high rate of wages. In another process of the same Art, dry-pointing, which is also executed with great rapidity, the wages earned by the workman reach from $7s.$ to $12s.$, $15s.$, and even, in some instances, to $20s.$ a day, whilst other processes in the same Art are carried on by children paid at the rate of $6d.$ per day.

Pin-making
Machine.

Before we offer those further reflections which the preceding analysis suggests, it may be convenient to place before the reader a brief description of a Machine for making pins invented by an American. It is highly ingenious in point of contrivance, and, in respect to its economical principles, will furnish a strong and interesting contrast with the Manufacture of pins by the human hand.

In this Machine, a coil of brass wire being placed on an axis, one end of this wire is drawn by a pair of rollers through a small hole in a plate of steel, and is held there by a forceps.

As soon as the Machine is put in action—

1. The forceps draws the wire on to a distance equal in length to one pin. A cutting edge of steel then descends close to the hole through which the wire entered and severs a piece equal in length to one pin.

Manu-
factures.

Sect. I.

2. The forceps holding this wire moves on until it brings the wire into the centre of a chuck fixed in a small lathe which opens to receive it. Whilst the forceps returns to fetch another piece of wire, the lathe revolves rapidly and grinds the projecting end of the wire upon a steel mill which advances towards it.

3. After this first or coarse pointing the lathe stops, and another forceps takes hold of the half-pointed pin (which is instantly released by the opening of the chuck) and conveys it to a similar chuck of another lathe which receives it and finishes the pointing on a finer steel mill.

4. This mill again stops and another forceps removes the pointed pin into a pair of strong steel clams, having a small groove in them by which they hold the pin very firmly. The end of this groove, which terminates at that edge of the steel clams which is intended to form the head of the pin, is made conical. A small round steel punch is now driven forcibly against the end of the wire thus clamped, and the head of the pin is partially formed by compressing the wire into the conical cavity.

5. Another pair of forceps now removes the pin to another pair of clams, and the head of the pin is completed by a blow from a second punch, the end of which is slightly concave.

Each pair of forceps returns as soon as it has delivered its burden, and thus there are always five pieces of wire at the same moment in different stages of advance towards a finished pin. The pins so formed are received in a tray, and whitened and papered in the usual manner. About sixty pins can thus be made by this Machine in one minute, but each process occupies exactly the same quantity of time in performing.

In order to judge of the value of such a Machine compared with hand labour, it would be necessary to know—1. to what defects pins so made are liable; 2. what advantages they possess over those made in the usual way; 3. what is the prime cost of a Machine for making them; 4. what is the expense of keeping it in repair; 5. what is the expense of moving it and attending to it.

Comparison
with pins
made by
hand.

Pins made by the Machine are more likely to bend, because as the head is punched up out of the solid wire, it ought to be in a soft state to admit of this process.

Pins made by the Machine are better than common ones, because they are not subject to losing their heads.

With respect to the prime cost of a Machine, it would be very much reduced if numbers should be required.

With regard to its wear and tear, experience only can decide the question; but it may be remarked, that the steel clams or dies in which the heads are punched up, will wear quickly unless the wire has been softened by annealing, and that if it has been softened the bodies of the pins will bend too readily. Such an inconvenience might be remedied, either by making the Machine spin the heads and fix them on, or by annealing only that end of the wire which is to become the head of the pin; but this would cause a delay between the operations, since the brass is too brittle when heated to bear a blow without crumbling.

On comparing the time occupied by the Machine with that stated in the analysis, we

Manu-
factures.

Sect. I.

find, except in the process of heading, if time alone is considered, that the human hand is more rapid. Three thousand six hundred pins are pointed by the Machine in one hour, whilst a man can point fifteen thousand six hundred in the same time. But in the process of heading the rapidity of the Machine is two and a half times that of the human hand.

It must, however, be observed, that the process of grinding does not require the application of force to the Machine equal to that of one man, for all the processes we have described are executed at once by the Machine, and one labourer can easily work it.

Such an
analysis
points out
the proper
direction of
improve-
ment.

One of the first advantages which suggests itself as likely to arise from a correct analysis of the expense of the several processes of any Manufacture, is the indication which it furnishes of the course in which improvement should be directed. If any method should be contrived of diminishing by one-fourth the time required for fixing on the heads of the pins, the expense of making them would be reduced about thirteen per cent., whilst a reduction of one-half the time employed in spinning the coil of wire out of which the heads are cut, would scarcely make any sensible difference in the cost of the Manufacture of the whole article. It is therefore obvious, that the attention would be much more advantageously directed to shortening the former than the latter process.

Division of
labour ap-
plied to Mind.

We have already alluded to a circumstance which may to some of our readers appear, perhaps, paradoxical, that the division of labour can be applied with equal success to mental operations, and that it ensures, by its adoption, the same economy of time. Perhaps a short account of its practical application, in the most extensive series of calculations ever executed, will offer an interesting illustration of this fact, whilst it at the same time affords an occasion for showing that the arrangements which ought to regulate the interior economy of a Manufactory, are founded on principles of deeper root than had been anticipated, and are capable of being usefully employed in paving the road to some of the sublimest speculations of the Human Mind.

In the midst of that excitement which accompanied the Revolution of France and the succeeding wars, the ambition of the Nation, unexhausted by a too fatal passion for military renown, was at the same time directed to the nobler and more permanent triumphs which mark the era of a People's greatness; which receive the applause of a grateful posterity long after their conquests have been wrested from them; and which perpetuate it to times when their existence as a Nation is told only by the page of History.

Amongst their enterprises of Science, the French Government was desirous of producing a series of Mathematical Tables of general use, which should facilitate the extension of the decimal system they had so recently adopted. They directed, therefore, their Mathematicians to construct "*le monument de Calcul, le plus vaste et le plus imposant qui eût jamais été exécuté ou même conçu.*"

Their most distinguished Philosophers, responding fully to their Country's call, created new methods for the laborious task, and a Work, completely answering the large demands of the Government, was produced in a remarkably short period of time.

M. Prony, to whom the superintendence of the whole was confided, in speaking of its commencement, observes: "*Je m'y livrai avec toute l'ardeur dont j'étois capable, et je m'oc-*

Manu- *“cupai d'abord du plan général de l'exécution. Toutes les conditions que j'avois à remplir* Sect. I.
 factures. *“nécessitoient l'emploi d'un grand nombre des calculateurs ; et il me vint bientôt à la pensée*
“d'appliquer à la confection de ces Tables la division du travail, dont les Arts de Commerce
“tirent un parti si avantageux pour réunir à la perfection de main-d'œuvre l'économie de la
“dépense et du temps.”

The ancient methods of computing Tables were quite inapplicable to such a proceeding. Great
 M. Prony therefore wished to avail himself of all the talent of his Country, and formed the French
 First Section of those who were to take part in this enterprise out of five or six of their Tables.
 most eminent Mathematicians.

First Section.—The duty of the First Section was to investigate amongst the various analytical expressions which could be found for the same function, that which was most readily adapted to simple numerical calculation by many individuals employed at the same time. This Section had little or nothing to do with the actual numerical work. When its labours were concluded, the formulæ, on the use of which it had decided, were delivered to the

Second Section.—This Section consisted of seven or eight persons having some considerable acquaintance with Mathematics, and their duty was to convert into numbers the formulæ put into their hands by the First Section, an operation of some labour ; and then to deliver out these formulæ to the members of the Third Section, and receive from them the finished calculations. The members of this Second Section had certain means of verifying these calculations without the necessity of repeating, or even of examining the whole of the work done by the Third Section.

Third Section.—The members of this Section, whose number varied from sixty to eighty, received certain numbers from the Second Section, and using nothing more than simple addition and subtraction, they returned to that Section the finished Tables. It is remarkable that nine-tenths of this Class had no further knowledge of Arithmetic than its first two rules which they were thus called upon to exercise, and that these persons were usually found more correct in their calculations, than those who possessed a more extensive knowledge of the subject.

When it is stated that the Tables thus computed occupy seventeen large folio volumes, some idea may perhaps be formed of the labour.

From that part executed by the Third Class, requiring the least knowledge and by far the greatest labour, and which may almost be termed mechanical, the First Class were entirely exempt. Such labour can always be purchased at an easy rate. The duties of the Second Class, although requiring it to execute considerable Arithmetical operations, were yet in some measure relieved by the higher interest necessarily felt in those more difficult operations.

The exertions of the First Class are not likely to require, upon another occasion, so much skill and labour as they did upon the first attempt at introducing such a method ; and when the completion of a Calculating Engine shall have produced a perfect substitute for the whole of the Third Section of computers, the attention of analysts will naturally be directed to render its mode of application most simple, by a new discussion of the methods of converting analytical formulæ into number.

Manu-
factures.

The proceeding of M. Prony in this celebrated system of calculation, much resembles that of a skilful person about to construct a cotton or silk mill, or any other similar establishment. Having from his own genius, or through the aid of his friends, found that some improved Machinery may be successfully applied to his pursuit, he makes drawings of his plans of the Machinery, and may himself be considered as constituting the First Section. He next requires the assistance of operative engineers capable of executing the Machinery he has designed, some of whom should understand the nature of the process to be adopted; and these constitute his Second Section. When a sufficient number of Machines have been made, a multitude of other operatives, possessed of a lower degree of skill, must be employed in using them, and these form the Third Section; and their work, and the just performance of the Machines, must be still superintended by the Second class.

Sect. I.

Arithmeti-
cal opera-
tions by
Machinery.

As the performance of Arithmetical calculations by Machinery may appear to our non-mathematical readers to be rather too large a postulate, and as it is connected with the subject of the *division of labour*, we shall endeavour in the course of a few lines to give them some slight perception of the manner in which it can be performed, and thus to remove a small portion of the veil which covers that apparent mystery.

Mathemati-
cal prin-
ciple.

That nearly all Tables of numbers which follow any law, however complicated, may be formed to a greater or less extent solely by the proper arrangements of the successive addition and subtraction of numbers befitting each Table, is a principle which we could only prove in the general to those well acquainted with Mathematics, but the mind will readily admit that it is not impossible by attending to the following example.

Let us consider the subjoined Table.

Terms of the Table.	Table.	1st Difference.	2d Difference.
1	1	3	2
2	4	5	2
3	9	7	2
4	16	9	2
5	25	11	2
6	36	13	2
7	49		

This is the beginning of a Table in very extensive use, which has been printed and re-printed very frequently in many Countries, and is called a Table of square numbers. Any number in the Table is found by multiplying the number which expresses the distance of that term from the commencement of the Table by itself; thus, 25 is the fifth term from the beginning of the Table, and 5 multiplied by itself, or by 5, is equal to 25. Let us now subtract each term of this Table from the next succeeding, and place the results in another column, which may be called 1st Difference column. If we again subtract each term of this first difference from the succeeding term, we find the result is always the number two. That such must always be the case, will appear to any person who takes the trouble to carry on the Table a few terms further. Now when once this is admitted as a known fact, it is quite clear that, provided the first term (1) of the Table, the first term (3) of the first difference, and the first term (2) of the second

Manu-
factures.

Sect. I.

or constant difference, are originally given, we can continue by simple addition the Table of square numbers to any extent. For the series of odd numbers may be formed by repeatedly adding the constant difference 2 to (3) the first of them, and we then necessarily have the series 3, 5, 7, &c.; and again by successively adding each of these to the first number (1) of the Table we produce the square numbers.

Having thus, we hope, thrown a little light upon the theoretical part, we will endeavour to show that the mechanical execution of such an engine is not so far removed from ordinary Machinery as might be conceived. Let the reader imagine three clocks placed on a table side by side, and having a thousand instead of twelve hours marked on the face of each, and every time a string is pulled, let them repeat the hours to which their hands point. Let him further suppose that two of the clocks, for the sake of distinction called A and B, have some mechanism by which the clock A advances the hour hand of the clock B one hour for each stroke it makes on its own bell; and let the clock B by a similar contrivance advance the hour hand of the clock C one hour for each stroke it makes upon its own bell. With such an arrangement, and having set the hour hand of the clock A to 2 o'clock, that of B to 3 o'clock, and that of C to 1 o'clock, let the reader imagine the strings of the repeating parts of the clocks pulled continually in the following order of succession. Pull the string of clock C; pull the string of clock B; pull the string of clock A.

Practical
illustration.

	Clock C Marks one.	1st Difference. Clock B Marks three.	2d Difference. Clock A Marks two.
Pull the string of C.	Strikes one.		
Pull the string of B.	{ The hour hand is advanced three, and the clock now marks four. }	Strikes three.	
Pull the string of A.		{ The hour hand is advanced two, and the clock now marks five. }	Strikes two.
Pull the string of C.	Strikes four.		
Pull the string of B.	{ The hour hand is advanced five, and the clock now marks nine. }	Strikes five.	
Pull the string of A.		{ The hour hand is advanced two, and the clock now marks seven. }	Strikes two.
Pull the string of C.	Strikes nine.		
Pull the string of B.	{ The hour hand is advanced seven, and the clock now marks sixteen. }	Strikes seven.	
Pull the string of A.		{ The hour hand is advanced two, and the clock now marks nine. }	Strikes two.
Pull the string of C.	Strikes sixteen.		
Pull the string of B.	{ The hour hand is advanced nine, & the clock now marks twenty-five. }	Strikes nine.	
Pull the string of A.		{ The hour hand is advanced two, and the clock now marks eleven. }	Strikes two.
Pull the string of C.	Strikes twenty-five.		
Pull the string of B.	{ The hour hand is advanced eleven, & the clock now marks thirty-six. }	Strikes eleven.	
Pull the string of A.		{ The hour hand is advanced two, and the clock now marks thirteen. }	Strikes two.
Pull the string of C.	Strikes thirty-six.		
Pull the string of B.	{ Advances the hour hand thirteen, & the clock now marks forty-nine. }	Strikes thirteen.	
Pull the string of A.			
&c.	&c.	&c.	&c.

Manu-
factures.

Sect. I.

If now only those hours struck or pointed at by the clock C be attended to and written down, it will be found that it produces the series of the squares of the natural numbers. Such a series could of course only be produced completely by this mechanism so far as the three first figures, but this is sufficient to give some idea of the construction, and was the point to which the first model of the Calculating Engine extended.

We have seen then that the effect of the *division of labour*, both in mechanical and in mental processes, is that it enables us to purchase for each process precisely that quantity of skill and knowledge which is required for it; we avoid employing any part of the time of a man who can get eight or ten shillings a day by his skill in tempering needles in turning a wheel which can be done for sixpence a day, and we equally avoid the loss of employing the invaluable time of an accomplished Mathematician in the lowest processes of Arithmetic.

The extent to which the *division of labour* can be carried seems not to be unlimited. We have already alluded in the first chapter to the case of making the tags of laces, in which it appeared that a saving of time occurred from uniting two processes in one operation. The *division of labour* cannot be successfully practised unless there exists a great demand for its produce, and it requires larger capital to be employed in those Arts in which it is used.

ON THE SIZE OF FACTORIES.

On examining the analysis* of the Art of pin-making, we find that ten individuals are employed in it, and supposing this arrangement to be such that the whole of the time of each person employed is fully occupied, it is at once apparent that to conduct an establishment for pin-making most profitably, the number of persons employed must be a multiple of ten. For if a person with small means has only sufficient capital to enable him to employ half that number of persons, they cannot each of them constantly adhere to the execution of one process, and if a Manufacturer employs any number not a multiple of ten, a similar result must ensue with respect to some portion of them.

Principle
relating to
the number
of persons
in a factory.

The same reasoning extends to all Manufactories which are conducted upon the principle of the *division of labour*, and we arrive at this conclusion, *when (from the peculiar nature of the produce of each Manufactory) the number of processes into which it is most advantageous to divide it is ascertained, as well as the number of individuals to be employed, then all other Manufactories which do not employ a direct multiple of this number, will produce the article at a greater cost.*

Large fac-
tories econo-
mize trans-
port of ma-
terial.

Hence arises one of the causes of the size of Manufacturing establishments which have increased with the progress of civilization.

But another circumstance which contributes to the same end arises also from the same cause. The material out of which the Manufactured article is produced, must in the

* We must again recall to the reader's memory that the analysis referred to is an approximative one, and that there are few factories in which every operative is at all times fully employed, although this is the object which they all strive to attain. We have given an individual instance as most likely to excite the attention, whilst we particularly wish to direct the reader to the general nature of the reasoning.

Manu-
factures.

Sect. I.

several stages of its progress be conveyed from one operator to the next in succession ; this can be done at least expense when they are all working in the same establishment. If the material is heavy, this reason acts with additional force ; but in cases where it is light, the danger arising from frequently removing it may render it desirable to have all the processes carried on in the same building. In the cutting and polishing of glass this is the case, whilst in the Art of needle-making, several of the processes are carried on in the cottages of the workmen. It is, however, clear that the latter plan, which is attended with some advantages to the family of the workmen, can be adopted only where there exists a sure and quick method of knowing that the work has been well done, and that the whole of the materials given out have been really employed.

The inducement to contrive Machines for any process of Manufacture increases with the demand for the article, and the introduction of Machinery on the other hand tends to increase the quantity produced.

An illustration of these principles may be found in the commencement of the Manufacture of patent net. The first Machines for weaving it were very expensive, costing from £1000 to £1200 or £1300. The possessor of one of these Machines although it greatly increased the quantity of lace he could produce, was yet unable, when working eight hours a day, to compete with the old methods. This arose from the large capital invested in the Machinery ; but he quickly perceived that with the same expense of fixed, and a small addition to his circulating capital, he could work the Machine during the whole twenty-four hours.

The profits thus realized soon induced other persons to direct their attention to the improvement of those Machines, and the price was considerably reduced at the same time that the rapidity of production of the patent net was increased. If Machines are kept working through the twenty-four hours, it is necessary that some person shall attend to admit the workmen at the time they relieve each other, and whether the porter or other servant so employed admit one person or twenty, his rest will be equally disturbed. It is also necessary occasionally to adjust or repair the Machine ; and this will be done much better by a workman accustomed to Machine-making, than by the operative who uses it. Now since the good performance and the duration of Machines depend to a very great extent upon correcting, as soon as it appears, any shake or imperfection in their parts, it will soon become apparent that a workman resident on the spot will economize the wear and tear of the Machinery. But in the case of a single lace-frame, or a single loom, this would be too expensive a plan. Here then arises another circumstance which tends to enlarge the extent of a factory. It ought to consist of such a number of Machines as shall occupy the whole time of one workman in keeping them in order, and in making any casual repairs ; if it is extended beyond this, the same principle of economy points out the necessity of doubling or tripling the number of Machines in order to employ the whole time of two or three skilful workmen.

Enable Ma-
chines to be
worked all
night.

Where one part of each operative's labour consists in the exertion of mere Physical force, as in Weaving and many similar Arts, it will soon occur to the Manufacturer, that if the loom or lace-frame were driven by a steam-engine, the operative might attend to two

Mode of
paying for
work in
mines in
Cornwall.

or more looms at once ; and since we already suppose that he has employed one or more operative engineers, he may so arrange the number of his looms that the charge of keeping them and the steam-engine in order, shall just fully occupy their time. One of the first effects will be that the steam-engine can drive the looms twice as fast as human force, and as each operative, when relieved from bodily labour, can attend to two looms, it will be found that one operative can now make as much cloth as four could do previously. This increase was greater than that which really took place at first, for the limit of the velocity of the parts of the loom depended upon the strength of the thread, and the quickness with which it commenced its motion : but an improvement was soon made by which the motion commenced slowly, and gradually acquired greater velocity than it was safe to give it at once. This improvement increased the speed from 100 to about 120 strokes per minute. Pursuing the same principles, the Manufactory becomes gradually so enlarged, that the expense of lighting during the night amounts to a considerable sum, and as there are already attached to the establishment persons who are up all night, and can therefore constantly attend to it, and also operative engineers to make and keep in repair any Machinery, the addition of an apparatus for making gas to light the factory introduces a new extension, at the same time that it contributes, by diminishing the expense of lighting, and the risk of accidents from fire, to render the production of the Manufactured article at a diminished cost.

Long before a factory has reached this extent, it will have been found necessary to establish an accountant's department, with clerks to pay the workmen, and to see that they arrive at their stated times ; and this department must be in communication with the agents who purchase the raw produce, and with those who sell the Manufactured article.

It would be of great importance, if in every large establishment the modes of paying the different persons employed could be so arranged, that each should derive advantage from the success of the whole, and that the profits of the individuals should advance as the factory itself produced profit, without the necessity of making any change in the wages agreed upon. This is by no means an easy arrangement to effect, and particularly amongst that class whose daily labour procures them their daily meal. The system which has long been pursued in working the Cornish mines, although not exactly fulfilling these conditions, yet possesses advantages which make it worthy of attention, as having considerably approached towards them, and as tending to render fully effective the faculties of all engaged in it.

Almost the whole of the work both above and below ground is contracted for. The manner of making the contract is nearly as follows : at the end of every two months the work which it is proposed to carry on during the next period is marked out. It consists of three kinds of work. 1. *Tutwork*, which consists in sinking shafts, driving levels, and making excavations ; this is paid for by the fathom in depth, or in length, or by the cubic fathom. 2. *Tribute*, which is payment for raising and dressing the ore, by means of a certain part of its value when merchantable. It is this species of payment which produces such admirable effects. The miners, who are to be paid in proportion to the richness of the vein, and the quantity of metal actually extracted from it, naturally become

Manu-
factures.

Sect. I.

quick-sighted in the discovery of ore, and in estimating its value; and it is their interest to avail themselves of every improvement that can bring it more cheaply to market.

3. *Dressing*. The tributors, who dig and dress the ore, can seldom afford to dress the coarser parts of that which they raise at their contract price; they therefore leave it, and it is again let out to persons, who agree to dress it at an advanced price.

The lots of ore to be dressed, and the works to be carried on, having been marked out for some days, and having been examined by the men, a kind of auction is held by the captains of the mine, in which each lot is put up, and bid for by different gangs of men. The work is then offered at a certain price to the lowest bidder, who rarely declines it at the rate proposed.

The tribute is a certain sum out of every twenty shillings' worth of ore raised, and may vary from threepence in the pound to fourteen or fifteen shillings. The rate of earnings in tribute is very uncertain; if a vein which was poor when taken becomes rich, the men earn money rapidly; and instances have occurred in which each miner of a gang has earned a hundred pounds in the two months. These extraordinary cases are perhaps of more advantage to the owners of the mine than even to the men, for they are always accompanied by some improved vein, and they greatly stimulate the skill and industry of the men.*

OF THE EFFECTS OF GREAT CAPITALS EMPLOYED IN MANUFACTURES

We have seen that the circumstance of the *division of labour* tends to produce cheaper articles; thus it increases the demand, and gradually, by the effect of competition, or the hope of increased gain, causes large capitals to be embarked in extensive factories. Let us now examine the influence of such accumulation of capital directed to one object. In the first place it enables the most important principle on which the division of labour rests to be carried almost to its extreme limits; not merely the precise amount of skill is purchased which is necessary for the execution of each process, but throughout every channel of its passage, from that in which the raw material is procured, to that by which the finished produce is conveyed into the hands of the consumer, the same system of economy of skill prevails. The result of this is necessarily a great reduction in the expense of the article which is brought to market. The quantity of work produced by a given number of people is, from such an extended arrangement, greatly augmented.

In many of the large establishments of our Manufacturing districts, substances are employed which are the produce of remote Countries, and which are in several instances almost peculiar to a few situations. The discovery of any new locality where such articles exist in abundance, is a matter of great importance to any establishment consuming them largely, and it has been found in some instances that the expense of sending persons to great distances purposely to ascertain such facts, and to collect such produce, has been amply repaid. Thus it has happened that the snowy mountains of

Send to dis-
tance for
materials.

* For a detailed account of the method of working the Cornish mines, see a paper by Mr. John Taylor, *Transactions of the Geological Society*, vol. ii. p. 309.

Manu-
factures.

Sweden and Norway, as well as the warmer hills of Corsica, have been almost stripped of one of their vegetable productions by agents sent expressly from one of our largest establishments for the dyeing of calicoes. Sect. I.

Every part
of raw ma-
terial em-
ployed.

Amongst the causes which tend to the cheap production of any article, and which require additional capital, may be mentioned the care which is taken to allow no part of the raw produce out of which it is formed to be absolutely wasted. An attention to this circumstance sometimes causes the union of two Trades in one factory, which might otherwise naturally have been separated. An enumeration of the Arts to which the horns of cattle are applicable, furnishes a striking example of this kind of economy. The tanner who has purchased the hides separates the horns, and sells them to the makers of combs and lanterns. The horn consists of two parts, an outward horny case, and an inward conical-shaped substance, somewhat intermediate between indurated hair and bone.

The first process consists in separating by means of a blow against a block of wood these two parts.

The horny exterior is cut into three portions by means of a frame saw.

1. The lowest of these next the root of the horn, after undergoing several processes by which it is rendered flat, is made into combs.

Instance,
Horns of
cattle.

2. The middle of the horn, after being flattened by heat, and its transparency improved by oil, is split into thin layers, and forms a substitute for glass in lanterns of the commonest kind.

3. The tip of the horn is used by the makers of knife-handles, and of the tops of whips, and for other similar purposes.

4. The interior or core of the horn is boiled down in water. A large quantity of fat rises to the surface, this is put aside, and sold to the makers of yellow soap.

5. The liquid itself is used as a kind of glue, and is purchased by the cloth-dressers.

6. The bony substance which remains behind is then sent to the mill, and being ground down is sold to the farmers for manure.

Besides these various purposes to which the different parts of the horn are applied, the clippings which arise in comb-making are sold to the farmer for manure at about one shilling a bushel. In the first year they have comparatively little effect, but during the next four or five their efficiency is considerable.

The shavings arising from the lantern-maker are of a much thinner texture, a few of them are cut into various figures and painted, and used as toys; for being hygrometric they curl up when placed in the palm of a warm hand. But the greater part of these shavings are sold to the farmers for manure, which from their extremely thin and divided form produces its full effect upon the first crop.

Middle-
men.

Another event which has arisen, in one Trade at least, from the employment of large capital, is that a class of middle-men, who were formerly interposed between the maker and the merchant, now no longer exists. In the printed-cotton trade this has arisen from two causes, the diminished cost of production in large establishments, although, perhaps, the most important, has not been the sole reason. In order to explain the other cause

Manu-
factures.

Set. I.

which has contributed to this change, we must advert to a principle of Political Economy which perhaps still requires a more enlarged discussion.

The *cost* of an article, at any given period, is stated to depend upon *the proportion between the supply and the demand*, which is true so far as the principle extends: but the *average cost* of any article through a long period, is stated to rest ultimately on the power of producing it and of selling it, with the ordinary profits of capital.

Now the cost of any article to the purchaser includes another element, which, although in most cases of little importance, is of great consequence in others.

The cost to the purchaser is the price he pays for any article, added to the cost of verifying the fact of its having that degree of goodness for which he contracted. In some cases the goodness of the article is evident on mere inspection, and in those cases there is not much difference of price at different shops. The goodness of loaf-sugar, for instance, can be discerned almost at a glance; and the consequence is, that the price of it is so uniform, and the profit upon it so small, that no Grocer is at all anxious to sell it; whilst, on the other hand, tea, of which it is exceedingly difficult to judge, and which can be adulterated by mixture so as to deceive the skill even of a practised eye, has a great variety of different prices, and is that article which every Grocer is most anxious to sell to his customers.

Cost to pur-
chaser is
price added
to verifica-
tion.

The expense of verification is, in some instances, so considerable, as to justify the deviation from well-established principles. Thus it has been found so difficult to detect the adulteration of flour and to measure its good qualities, that, contrary to the maxim, *that Government can generally purchase any article at a cheaper rate than that at which they can Manufacture it*, it has been found more economical to build extensive flour mills, (such are those at Deptford,) and to grind their own corn, than to verify each sack purchased, and to employ persons in continually devising methods of detecting the new modes of adulteration which might be resorted to. This principle has had its influence on the cotton trade. Formerly, when pieces of calico were woven in the cottages of the operatives, there existed a class of men who travelled about and purchased them, and collected them in large quantities, for the purpose of selling them to the exporting merchant. But the middle-man was obliged to examine each piece in order to know that it was perfect, and of full measure. Now, although the greater part of the operatives might be depended upon, yet the fraud of the few would make this examination necessary. For the value of character, although great in any circumstances of life, can never be so fully experienced by persons possessed of small capital as by those employing much larger sums. Any single cottager might hope if he were detected by one purchaser, that the fact would not become known to all the rest; whilst the larger the sums of money for which any merchant deals, the more is his character for punctuality studied and known by others. Thus it happens that high character supplies the place of an additional portion of capital; and the merchant, in dealing with the great Manufacturer, is saved from the expense of verification by his confidence that the loss, or even the impeachment of the merchant's character, would be attended with greater pecuniary detriment to him than any profit upon a single transaction could compensate.

Sometimes
cheaper to
make than
to verify.

Manu-
factures.
Character
instead of
verification.

The powerful influence of established character in producing confidence operated in a very marked manner at the time of the exclusion of British Manufactures from the Continent during the last war. One of our largest establishments had been in the habit of doing extensive business with a house in the centre of Germany, but on the closing of the Continental ports against our Manufactures, heavy penalties were inflicted on all those who contravened the Berlin and Milan Decrees. The English Manufacturer continued to receive orders, with directions how to consign them, and appointments for the time and mode of payment, in letters, the hand-writing of which was known to him, but which were never signed, except by the Christian name of one of the firm, and even in some instances they were without any signature at all. These orders were executed, and in no instance was there the least irregularity in the payments.

Price also
depends on
the number
of persons
holding the
supply.

Before we quit the subject of the *price* of a commodity, we must advert to two other circumstances which influence its amount. If the supply, or present stock in hand, is entirely in the possession of one person, he will naturally endeavour to put such a price upon it as shall produce by its sale the greatest quantity of money; but he will be guided in this estimate of the price at which he will sell it both by the knowledge that increased price will cause a diminished consumption, and by the desire to realize his profit before a new supply shall reach the market. If however the same stock is in the hands of several dealers there will be competition between them, arising partly from their different views of the duration of the present state of supply; and partly by their own peculiar circumstances with respect to the employment of their capital.

And on the
durability
of the ar-
ticle.

Again, if the commodity is itself of a perishable nature, such for example as a cargo of ice imported into the port of London from Norway a few Summers since, then time will supply the place of competition, and whether it is in the possession of one or of many persons it will scarcely reach a monopoly price.

POSITION OF FACTORIES.

It is found in every Country that the situation of large Manufacturing establishments is confined to particular districts. In the earlier history of a Manufacturing community, before cheap modes of transport have been extensively introduced, it will almost always be found that the article will be manufactured near those spots in which Nature has produced the raw material.

Factories
placed near
water
power,

In the heavier articles, and in those the value of which depends more upon the material than upon the labour expended on it, this will most frequently be the case. Most of the metallic ores being exceedingly heavy, and being mixed up with large quantities of weighty and useless materials, must be smelted at no great distance from the spot which produces them; fuel and power are the requisites for reducing them, and any considerable fall of water in the vicinity will naturally be resorted to for aid in all the coarser exertions of Physical force; for pounding the ore, blowing the furnaces, or for hammering and rolling out the iron. There are indeed peculiar circumstances which will modify this. Iron, coal, and limestone usually occur in the same district; but the

or coals for
steam,

Manu-
factures. union of the fuel in the same locality with the ore does not occur with respect to other Sect. I.
metals. In Cornwall there exist mines of copper and of tin, but none of coal. The copper ore which requires the largest quantity of fuel for its reduction is conveyed by ships to the coal fields of Wales, and is smelted at Swansea; whilst the vessels which convey it take back cargoes of coals to supply the steam-engines for draining the mines, and to smelt the tin, which requires a much less quantity of fuel for that purpose.

Rivers passing through districts rich in coal and metals, will form the first high roads or rivers for
carriage. for the conveyance of weighty produce to stations in which other conveniences present themselves for the further application of human skill. Canals will succeed, or lend their aid to these; and the yet unexhausted applications of Steam and of Gas hold out a hope of attaining almost the same advantages for Countries to which Nature seemed for ever to have denied them. Manufactures, Commerce, and Civilization ever follow the line of new and cheap communications. Twenty years ago the Mississippi poured the vast volume Mississippi. of its waters in lavish profusion through thousands of miles of Countries, which scarcely supported a few wandering and uncivilized Tribes of Indians. The power of the stream seemed to set at defiance the efforts of man to ascend its course, and as if to render the task still more hopeless, immense trees torn from the surrounding forests were planted in its bottom, forming in some places a barrier, in others the nucleus of a bank, and accumulating in the same spot, which but for accident would have been free from either, the difficulties and dangers of sand-banks and of rocks. Four months of incessant toil could scarcely convey a small bark with its worn-out crew two thousand miles up this stream. The same voyage is now performed by large vessels impelled by steam, carrying hundreds of passengers enjoying all the comforts and luxuries of civilized life, in the short period of ten days. Instead of the hut of the Indian, and the far more unfrequent log-house of the thinly scattered settlers, villages, towns, and cities have arisen on its banks; and the same engine which stemmed the force of these powerful waters, will probably tear from their bottom the obstructions which have hitherto impeded and rendered dangerous their navigation.

Although the price of any article may be reduced in its ultimate analysis to the quantity of *labour* by which it was produced, yet it is usual in a certain stage of the Manufacture of most substances to call them by the term *raw material*. Thus iron when Of raw ma-
terial. reduced from the ore and rendered malleable, is in a state of preparation for a multitude of useful purposes, and is the *raw material* out of which most of our tools are made. In this stage but a moderate quantity of *labour* has been expended on the substance, and it becomes an interesting subject to trace the various proportions in which *raw material* and *labour* are united to constitute the value of many of the productions of the Arts.

Gold-leaf consists of a small portion of the metal beat out to so great a degree of thinness, as to allow a greenish-blue light to be transmitted through its pores. About 400 square inches of this are sold in the form of a small book, containing 25 leaves of gold, for 1s. 6d. In this case, the raw material, or gold, is worth rather less than two-thirds Proportions
between raw
material
and labour, of the manufactured article. In the case of silver-leaf the labour considerably exceeds

Manu-
factures.

the value of the material. A book of fifty leaves, covering above 1000 square inches, is sold for 1*s.* 3*d.*

Sect. I.

Gold chains
of Venice.

In the fine gold chains made at Venice, we may trace in the various prices and sizes the relative influence of the two causes. The sizes of these chains are known by numbers, the smallest being originally No. 1, and the numbers 2, 3, 4, &c. each increasing in size. The following Table shows the numbers and the prices of those now made.* The first column is the number by which the chain is known, the second expresses the weight in grains of one inch in length of each chain, the third column shows the number of links in one English inch, and the last expresses the price in francs of a Venetian braccio, or about two English feet of each chain.

VENETIAN GOLD CHAINS.

No.	Weight of one inch. Grains.	Number of links in one inch.	Price of a Venetian Braccio, equal to 2 feet $\frac{1}{2}$ inch English.
0	.44	98 to 100	60
1	.56	92	40
1 $\frac{1}{2}$	.77	88	26
2	.99	84	20
3	1.46	72	20
4	1.61	64	21
5	2.09	64	23
6	2.61	60	24
7	3.36	56	27
8	3.65	56	29
9	3.72	56	32
10	5.35	50	34
24	9.71	32	60

In watch
balance
spring.

Amongst these chains that numbered 0, and that numbered 24, are exactly of the same price, although the quantity of gold in the latter is twenty-two times as much as in the former. The difficulty of making the smallest chain is so great, that the women who make it cannot work above two hours at a time. As we advance from the smaller chain, the proportionate value of the work to the worth of the material becomes less and less, until at the numbers 2 and 3, these two elements of its cost balance each other, after which the difficulty of the work decreases, and the value of the material increases. The quantity of labour applied to these chains is, however, incomparably less than that which is applied to some of the Manufactures of iron. In the case of the smallest chain the value of the labour is not above thirty times that of the gold. The pendulum spring of a watch which governs the vibrations of the balance, costs at the retail price two-pence, and weighs fifteen hundredths of a grain, whilst the retail price of a pound of the

* This was in 1828; a still finer chain is now (1831) manufactured.

Manu- best iron, the raw material out of which above fifty-thousand such springs may be made, Sect. I.
 factures. is exactly the same sum of two-pence.

OF THE PROPER CIRCUMSTANCES FOR THE APPLICATION OF MACHINERY.

The first object of Machinery, and that which gives to it its most extensive utility, is the cheap production of the articles to which it is applied. Wherever it is required to produce a great multitude of articles, all of exactly the same kind, the proper time has arrived for the construction of tools or Machines by which they may be Manufactured. If only a few pairs of cotton stockings should be required in a Country, or in circumstances in which it is impossible to purchase them, it would be an absurd waste of time, and of capital, to construct a stocking-frame to weave them, when for a few pence four steel wires may be procured by which they may be knit. If, on the other hand, many thousand pairs were wanted, the time employed, and the expense incurred in constructing a stocking-frame, would be more than repaid by the saving of time in making that large number of stockings. The same principle is applicable to the copying of letters: if only three or four copies are required, the pen and the human hand furnish the cheapest resource, but if hundreds of thousands of copies are required, the Machinery of a Printing establishment is the most economical method of accomplishing the object.

Principles which render the application of Machinery suitable.

There are, however, many cases in which Machines or tools must be made, where economical production is not the most important object. Whenever it is required to produce a few articles, parts of Machinery for instance which must be executed with the most rigid accuracy, it becomes nearly impossible to fulfil this condition, even with the aid of the most skilful workmen. In such circumstances it is necessary to make tools for the purpose, although those tools should, as frequently happens, cost more in constructing than the things they are destined to make.

Another instance of the just application of Machinery even at an increased expense, arises where the shortness of time in which the article can be produced, has an important influence on its value. In the publication of a daily newspaper, it frequently happens that the debates in the Houses of Parliament are carried on to three and four o'clock of the morning, that is to within a very few hours of the time of the publication of the newspaper. The speeches must be taken down by Reporters, transcribed by them, conveyed to the establishment of the newspaper, perhaps at the distance of two miles, set up by the Compositor, the press corrected, and papers printed off before the Public can read them. Some of these periodicals have a circulation of from five to ten thousand daily. Supposing eight thousand to be wanted, and that they could be printed only at the rate of five hundred per hour, (on one side,) which was the greatest number two journeymen and a boy could take off by the old hand-presses, it would require sixteen hours for the complete edition, and the news conveyed to the purchasers of the latest portion of the edition would be out of date before they could receive it. To obviate this difficulty, the paper was obliged to be set up in duplicate, and sometimes, when late, in triplicate; but the improvements in the printing Machines have been so great, that four thousand copies are now printed in an hour.

Printing quickly.

Manu-
factures.
Conveyance
of letters.

Sect. I.

The conveyance of letters is another instance in which the importance of saving time would allow of great expense in any new Machinery for its accomplishment. There is a natural limit to the speed of horses which even the greatest improvements in the breed, aided by an increased perfection in our public roads, can never surpass; and from which perhaps we are at present not very remote. When we reflect upon the great expense of time and money which the last refinements of a Theory or an Art usually require, it is not unreasonable to suppose the period has arrived in which the substitution of Machinery for such purposes ought to be tried.

The post bag despatched every evening by the mail to one of our largest cities, Bristol usually weighs less than a hundred pounds. Now the first reflection which naturally presents itself is, that in order to transport these letters a hundred and twenty miles, a coach and apparatus weighing above thirty hundred weight is put in motion, and also conveyed over the same space.*

It is obvious that amongst the conditions of Machinery for accomplishing such an object, it would be desirable to reduce the weight of matter to be conveyed with the letters; it would also be desirable to reduce the velocity of the animal power employed, because the faster a horse is driven, the less weight he can draw. Amongst the variety of contrivances which might be imagined, we will mention one which, although by no means free from objections, fulfils some of the prescribed conditions, and is not a purely theoretical speculation, since we have seen on an extremely limited scale some few experiments upon it.

Let us imagine a series of high pillars erected at frequent intervals, perhaps every hundred feet, as nearly as possible in a straight line between the two post towns. An iron or steel wire of some thickness must be stretched over proper supports fixed on each of these pillars, and terminating at the end of every three or five miles, as may be found expedient, in a very strong support, by which it may be stretched. At these points a man ought to reside in a small station-house. A narrow cylindrical tin case to contain the letters might be suspended by two wheels rolling upon this wire; these might be so constructed as to enable them to pass unimpeded by the fixed supports of the wire. An endless wire of much smaller size must pass over two drums, one at each end. This wire should be supported on rollers, fixed to the supports of the great wire, and at a short distance below it. With this arrangement there would be the two branches of the smaller wire always accompanying the larger one, and the attendant at either station might, by turning the drum, cause these two branches of the small wire to move with great velocity in opposite directions. In order to convey the cylinder which contains the letters, it would only be necessary to attach it by a string or by a catch to either of the branches of the endless wire. Thus it would be conveyed speedily to the next station, where it would be removed by the attendant to the commencement of the next wire, and thus transmitted on.

* It is true that the transport of letters is not the only object which this apparatus answers, but the transport of passengers, which is a secondary object, does in fact put a limit to the velocity of that of letters, which is the primary one.

Manu-
factures.

Sect. I.

It is not our intention to enter into the details which this or some similar plan would require. It is sufficient to observe that it is attended with its difficulties, but that when they are overcome, it will present many advantages besides velocity. For if an attendant reside at each station, the additional expense of having two or three deliveries of letters every day, and even of sending expresses at any moment, will be comparatively trifling, and it is not impossible that the stretched wire may itself be available for a species of telegraphic communication yet more rapid.

We shall mention one other instance in which the object to be obtained is so important, that although it might be rarely wanted, yet Machinery for that purpose would justify considerable expense. A vessel to contain men, and to be navigated at some distance below the surface of the sea, would in many circumstances be almost invaluable. Such a vessel evidently could not be propelled by any engine requiring the aid of fire. If, however, by condensing air into a liquid, and carrying it in that state, a propelling power could be procured sufficient for moving the vessel through a considerable space, the expense would scarcely render its occasional employment impossible.

Submarine
navigation.

The power of inventing mechanical contrivances and of combining Machinery does not appear, if we may judge from the frequency of its occurrence, to be a rare gift; and amongst the vast multitude of inventions which have been produced almost daily for a series of years, a large part have failed from the imperfect nature of the first trials; whilst a still larger portion, which had escaped the mechanical difficulties, have failed, because the economy of their operations had not been attended to.

Invention
in Mecha-
nics not
difficult.

To produce movements even of a complicated kind is not difficult. There exist a great multitude of known contrivances for all the more usual wants, and if the exertion of moderate power is the end of the mechanism to be contrived, it is possible to construct the whole Machine upon paper, and to judge of the proper strength to be given to each part as well as to the framework which supports it, and of its ultimate effect, long before a single part of it has been executed. In fact, all the contrivance and all the improvements ought to be made in the Drawings. On the other hand, there are circumstances dependent upon Physical or Chemical properties for which no drawings will be of any use. These are the legitimate object of direct trials.

Proper
subjects for
drawings.

For example, if the ultimate result of an engine is to be that it shall impress letters upon a copper-plate by means of steel punches pressed into it. All the mechanism by which the punches and the copper are to be moved at stated intervals, and brought into contact, is entirely within the province of Drawing, and the Machinery may be arranged entirely upon paper. But a doubt may reasonably spring up whether the bur that will be raised round the letter which has been punched upon the copper may not interfere with the proper action of the punch for the letter which is to be punched next adjacent to it. It may also be feared that the act of punching the second letter, if it be sufficiently near to the first, might distort the form of that first figure. And if neither of these evils should arise, still the burs produced by the punching might be expected to interfere with the goodness of the impression produced by the copper-plate, and the plate itself, after having all but its edge covered with figures,

Proper sub-
jects for ex-
periments.Punching
letters in
copper.

Manu-
factures.

might, from the unequal condensation which it must suffer in this process, change its form, so as to render it impossible to take off impressions from it. It is impossible by any Drawings to solve these difficulties, experiment alone can determine their nature. Such experiments have been made, and it is found that if the sides of the steel punch are nearly at right angles to the face of the letter, a very inconsiderable bur is produced ;—that at the depth which is sufficient for copper-plate printing, no distortion of the adjacent letters takes place, although those letters are placed very close to each other ;—that the small bur which arises may easily be scraped off ;—and that the copper-plate is not distorted by the condensation of the metal, and is perfectly fit to print from, after it has undergone this process.

The next stage in the progress of an invention after the Drawings are finished, and the preliminary experiments have been made, if any such should be requisite, is the execution of the Machine. It can never be too strongly impressed upon the minds of those who are devising new Machines, that to make the most perfect Drawings of every part tends essentially both to the success of the trial, and to economy in arriving at the result. The actual execution from the working Drawings is comparatively an easy task, provided always that good tools are employed and that methods of working are adopted, in which the perfection of the part constructed depends less on the personal skill of the workmen, than upon the certainty of the methods they employ.

Causes of
failure in
new Ma-
chines.

The causes of failure in this stage most frequently arise from errors in the preceding one, and it is sufficient merely to indicate a few of their sources. They usually arise from having neglected to take into consideration that metals are elastic, and not perfectly rigid. A steel cylinder of small diameter must not be considered as an inflexible rod ; but in order to ensure its perfect action as an axis, it must be supported at proper intervals. Again, the strength and stiffness of the framing which supports the mechanism must be carefully attended to. It should always be recollected that the addition of superfluous matter to the immovable parts of a Machine, is not accompanied with the same evil that arises when the moving parts are too heavy ; for thus no additional momentum is generated.

The stiffness of the framing of a Machine draws after it another important advantage. If the bearings of the axes (those places at which they are supported) are originally placed in a straight line, they will continue so, whereas if the framework itself changes its form, although ever so slightly, considerable friction will immediately arise. This effect is so well understood in the districts in which our spinning factories are numerous, that in estimating the expense of working a new factory, it is allowed that five per cent. on the power of the steam-engine will be saved if the building is fire-proof. This saving arises entirely from the circumstance that the greater strength and rigidity of a fire-proof building allow the long shafts or axes which drive the Machinery to be unimpeded by the friction which would arise from the slightest deviation in any of the bearings.

It is quite a mistaken idea to suppose that any imperfect work is good enough for a trial. If the experiment is at all worth trying, it ought to be tried with all the advantages of which the state of Mechanical Art admits ; for an imperfect trial may cause an idea to

Manu-
factures.

be given up which better workmanship might have proved to be practicable. On the other hand, when once its success has been established with good workmanship, it will be easy to ascertain that degree of perfection which is necessary for its due action.

Sect. I.

It is partly owing to this circumstance, *the imperfection of the original trials*, and partly owing to the gradual improvement in the Art of making Machinery, that many inventions which have been tried and have been given up in one state of Art, have at another period been eminently successful. The idea of printing by means of movable types has probably suggested itself to the imagination of many men conversant with impressions taken either from blocks or seals. We find amongst the instruments discovered in the remains of Pompeii and Herculaneum, stamps consisting of letters formed out of one piece of metal. The idea of separating these and recombining a multitude of similar ones for the purpose of stamping a book, instead of the initials of its owner, could scarcely have failed to have occurred to many, and would certainly have been almost immediately rejected by those best versed in the Mechanical Arts of that time: for any workman of those days would have instantly perceived the impossibility of producing many thousand pieces of metal fitting so perfectly, and ranging so uniformly as the types which are used for printing. The principle of the press which bears the name of Bramah, was known about a century and a half before the Machine to which it gave rise existed; but the imperfect state of Mechanical Art in the time of its discoverer would have effectually deterred him, if it had occurred to his mind, from attempting to apply it as an instrument for exerting force.

Failure
may occur
from imper-
fect state of
Mechanical
Arts.

These considerations prove the propriety of repeating, at the termination of intervals during which the Art of making Machinery has undergone any great improvement, the trials of methods which have previously failed, although they were founded upon just principles.

When the Drawings have been properly made, and the Machine well executed, and when the work it produces possesses all the qualities which were anticipated, still the invention may fail; that is, it may fail of being brought into general practice. This will most frequently arise from the circumstance of its producing its work at a greater expense than that at which it can be made by the old methods.

Whenever the new, or improved Machine, is intended to become the basis of a Manufacture, it is essentially requisite that the whole expense of producing the article by its means should be fully considered before its construction is undertaken. It is almost always very difficult to make this estimate of the expense; but the more complicated the Machinery the less easy the task, and in cases of great complexity and extent of Machinery it is almost impossible. It has been estimated roughly, that the expense of making the first individual of any newly-invented Machine will cost about five times as much as the construction of the second, an estimate which is perhaps sufficiently near the truth. If the second Machine is to be made precisely like the first, the same Drawings and the same patterns will suffice; but if, as usually happens, some improvements have been suggested by the experience of the first, more or less of these must be altered. When, however, two or three Machines have been completed, and many more

Compara-
tive expense
of first trial.

Manu-
factures.

are wanted, they can usually be produced at much less than one-fifth of the expense of the original invention. The Arts of contriving, of Drawing, and of executing, do not usually reside in their greatest perfection in one individual, and in this, as in other Arts, *the division of labour* must be applied. The best advice which could be offered to a projector of any mechanical invention is to employ a respectable Draughtsman, who, if he has had a large experience in his profession, will be able to assist him in finding out whether his contrivance is new, and who will then make working Drawings of it. The first step, the ascertaining whether the contrivance has the merit of novelty, is most important, and it is not easy to get satisfactory evidence upon this point. It is one also on which projectors are often singularly negligent.

Sect. I.

Mechanical
projectors
frequently
ignorant.

There is, perhaps, no trade or profession existing, in which there is so much quackery, so much ignorance of the Scientific principles, and of the History of the Art with respect to its resources and extent, as is to be met with amongst mechanical projectors. The self-constituted Engineer, dazzled with the beauty of some, perhaps, really ingenious contrivance, assumes his new profession with as little conjecture that previous instruction, that thought and painful labour are necessary to its successful exercise, as does the Statesman or the Senator. Much of this false confidence arises from the improper estimate which is entertained of the difficulty of the invention of mechanical contrivances; and it is of great importance, both for the individuals and for the families of those who are thus led away from more suitable pursuits, the dupes of their own ingenuity and of the popular voice, to convince both parties that the invention of new contrivances by no means requires talents of the highest order, and that the power of making new mechanical combinations is a possession common to a multitude of minds. It is still more important that they should be convinced that the great merit and the great success of those who have succeeded in such affairs, has arisen from, and was almost entirely due to, the unremitted perseverance with which they concentrated upon the successful Machine the skill and knowledge which years of study had matured.

It is a maxim equally just in all Arts and in every Science, that *the man who aspires to fortune or to fame by new discoveries, must be content to examine with care the knowledge of his contemporaries, or to exhaust his efforts in inventing again what he will most probably find has been better executed before.*

DURATION OF MACHINERY.

The time during which a Machine will continue effectually to perform its work, will depend mainly upon the perfection with which it was originally constructed, upon the care taken to keep it in proper repair, particularly to correct every shake or looseness in the axes, and upon the small mass and slow velocity of its moving parts. Every thing approaching to a blow, all sudden change of direction is injurious. Engines for producing power, such as wind and water-mills and steam-engines, usually last a long time;*

* The return which ought to be produced by a fixed steam-engine employed as a moving power is frequently estimated at ten per cent. on its cost.

Manu-
factures.

Sect. I.

but Machinery for producing any commodity in great demand is of short-lived duration. It is seldom that Machinery of this class wears out; new improvements, by which the same operations can be executed either more quickly or better, generally supersede it long before that period arrives: indeed, to make such an improved Machine profitable, it is usually reckoned that in five years it ought to have paid itself, and in ten to be superseded by a better.

The effect of improvements in Machinery seems incidentally to increase production through a cause which may be thus explained. A Manufacturer making the usual profit upon his capital, which he has invested in looms or other Machines in perfect condition, the market price of making each of which is a hundred pounds, invents some improvement. But this is of such a nature that it cannot be added to his present engines. He finds upon calculation, that at the rate at which he can dispose of his Manufactured produce, each new engine would repay the cost of its making, together with the ordinary profit of capital, in three years: he also concludes from his experience of the trade, that the improvement he is about to make will not be generally adopted by other Manufacturers before that time. On these considerations, it is clearly his interest to sell his present engines, even at half-price, and construct new ones on the improved principle. But the purchaser who gives only fifty pounds for the old engines, has not so large a fixed capital invested in his factory as the person from whom he purchased them, and as he produces the same quantity of the Manufactured article, his profits will be larger. Hence the price of the commodity will fall, not only in consequence of the cheaper production by the new Machinery, but also by the more profitable working of the old, when sold at a reduced price. This change can be only transient, for a time will arrive when the old Machinery, although in good repair, must become worthless. The improvement which took place not long ago in frames for making patent net was so great, that a Machine, in good repair, which had cost £1200, sold a few years after for £60; during the great speculations in that trade, the improvements succeeded each other so rapidly, that Machines which had never been finished were abandoned in the hands of their makers, because new improvements had superseded their utility.

The duration of any commodity seems to influence its cost in a permanent manner. We have already stated that what may be called the momentary price of any commodity depends upon the proportion existing between the supply and demand, and also upon the cost of verification. The average price during a long period will depend upon the labour required in producing and bringing it to market, as well as upon the average supply and demand, but it will also be influenced by the *durability of the article Manufactured*. There are many articles in common use which are destroyed in using: thus a phosphorus match, a sheet of letter paper, and a segar, can never be used twice. There are others, few perhaps in number, which never wear out; the harder precious stones, when well cut and polished, are of this latter class. The fashion of the gold or silver mounting in which they are set may vary with the taste of the Age, and such ornaments are constantly exposed for sale as second-hand, but the gems themselves when removed from their supports are never so considered. A brilliant, which has successively

Price of a
commodity
perma-
nently in-
fluenced by
its durabi-
lity.

graced the necks of a hundred beauties, or glittered for a century upon Patrician brows, will be weighed by the diamond merchant in the same scale with another fresh from its native repository, which has just escaped from the wheel of the lapidary, and will be purchased or sold by him at the same price per carat. The great mass of commodities is intermediate in its character between these two extremes, and the periods of respective duration are very various. It is evident that those things which are consumed in the act of using them, can never have an average price which is less than that of the labour of bringing them to market. They may for a short time be sold for less, but their production must soon, under such circumstances, cease altogether. On the other hand, if an article never wears out, the consequence will be that its price may continue *permanently* below the cost of the labour expended in producing it, and the only consequence will be that no further production will take place. Its price will continue to be regulated by the relation of the supply to the demand; and should that at any after time rise, for a considerable period, above the cost of production, it will again be Manufactured. Articles become old from actual decay or wearing out of their parts; from improved modes of constructing them; or from changes in their form and fashion required by the varying taste of the Age. Under the latter two circumstances, their utility is but little diminished, and being less sought after by the classes who have hitherto employed them, they are sold at a reduced price to a class of Society rather below that of their former possessors; thus a taste for luxuries is propagated downwards in Society, and after a short period, the numbers who have thus acquired new wants are sufficient to excite the ingenuity of the Manufacturer to reduce the cost of making them, who thus benefits himself by the extended scale. Many articles of furniture, such as well-made tables and chairs, are thus found in the rooms of those who would have been quite unable to have purchased them when new; and we find constantly, even in the houses of the more opulent, large looking-glasses which have passed successively through many possessors, changing only the fashion of their frames; and in some instances this alteration is omitted, and an additional coat of gilding saves them from the character of being second-hand.

Manu-
factures.
Diamonds.
Looking-
glasses.

There is a peculiarity in looking-glasses with reference to this principle. They are most frequently injured by violence, and the peculiarity is, that unlike most other articles when broken, they are still of some value. If a large mirror is accidentally cracked, it is immediately cut into two or more smaller ones, each of which may be perfect. If the degree of violence is so great as to break it into many pieces, these smaller pieces will be cut into squares for dressing-glasses, and if the silvering is injured, it can either be resilvered or used as plate glass for windows. The addition from our Manufactories to the stock of plate-glass in the Country is annually about two hundred and fifty thousand square feet. It would be very difficult to estimate the quantity annually destroyed or exported, but it is probably small, and the effect of these continual additions is seen in the diminished price and increased consumption of the article. Almost all the better order of shop fronts are now glazed with it. If it were quite indestructible the price would gradually diminish, and unless an increased demand arose from new

Manu- uses or a greater number of customers, a single Manufactory, unchecked by competition, *Sect. I.* would ultimately be obliged to shut up, driven out of the market by the permanency of its own productions.

The relative value of the same Manufacture in different Countries being always an interesting inquiry, we have given the following Table.

Comparative Price of Plate Glass at the Manufactories of London, Paris, and Berlin.

Height.	Breadth.	London. 1827.			Paris. 1825.			Berlin. 1828.		
Inches.	Inches.	£.	s.	d.	£.	s.	d.	£.	s.	d.
16	16	0	17	6	0	9	9	0	5	5
30	20	2	6	10	2	2	0	1	14	0
50	30	6	12	10	11	0	0	10	2	0
60	40	13	9	6	26	11	0	25	5	0
76	40	19	3	0	42	11	0	40	17	0
90	50	34	12	9	82	18	0			
100	75	74	5	10	269	8	0			
120	75	97	15	9	524	18	0			

The price of silvering these glasses is 20 per cent. on the cost price for English plate, and 10 per cent. on the cost price for Paris and Berlin plates.

OF COMBINATIONS AMONGST MASTERS OR WORKMEN.

There exist amongst the operatives of almost all classes certain rules or laws which govern their actions towards each other and towards their employers. But besides these general principles, there are usually others peculiar to each factory, which have arisen in many instances for the mutual convenience of the several parties engaged in them. Such rules are little known except to those actually pursuing the several trades, and as it is of importance that their advantages and disadvantages should be canvassed, we shall offer a few remarks upon some of them. The principles by which such laws should be tried are,

1st. *That they conduce to the general benefit of the whole of the persons employed.*

2dly. *That they prevent fraud.*

3dly. *That they interfere as little as possible with the free agency of each individual.*

It is usual in many workshops, that on the first entrance of a new journeyman, he shall pay a small fine to the rest of the men. It is clearly unjust to insist on this payment, and when it is spent in drinking, which is unfortunately too frequently the case, it is injurious. The reason assigned for the demand is, that the new comer will require some instruction in the habits of the shop, and in the places of the different tools, and will thus waste the time of some of his companions until he is instructed. If this fine

Rule of
particular
factories.

**Manu-
factures.** were added to a fund managed by the workmen of the establishment, and divided at given periods, or destined for their relief in sickness, it would be less objectionable, since its tendency would be to check the too frequent change of the men from one shop to another. But it ought, at all events, not to be compulsory, and the advantages to be derived from the fund to which he is invited to subscribe ought to be the workman's inducement.

In many workshops, the workmen, although employed in totally different parts of the objects Manufactured, are yet dependent in some measure on each other. Thus a single smith may be able to forge in one day enough work to keep four or five turners employed during the next. If from idleness or intemperance, the smith neglects his work, and does not furnish the usual supply, the turners (supposing them paid by piece-work) will have their time partly unoccupied and their gains consequently diminished. It is reasonable in such circumstances that a fine should be levied, in order to prevent their recurrence; but it is desirable that the master should have concurred with his workmen in establishing such a rule, and that it should be shown to each individual previous to his engagement; and it is very advisable that such fine should not be spent in drinking.

**Premium
for remark-
able skill.**

In some establishments it is customary for the master to give a small gratuity whenever any workman has exercised a remarkable degree of skill, or has economized the material employed. Thus in splitting horn into layers for lanterns, one horn usually furnishes from five to eight layers; but if a workman splits one horn into ten or more, he receives a pint of ale from the master. Such regulations, when judiciously made, are very desirable, as they tend to promote skill amongst the operatives, profit to the masters, and diminished cost to the consumers.

In some few factories, in which the men are paid by piece-work, it is usual, when any lot of work delivered in by a workman is rejected by the master on account of its being badly executed, to fine the delinquent. Such a practice tends to remedy one of the evils attendant upon that mode of payment, and greatly aids the master, since his own judgment is thus supported by competent and unprejudiced judges.

**Association
to fix the
relative
value of
work.**

There are Societies formed amongst larger bodies of workmen, and also by the masters engaged in the same branch of trade, which have other objects in view; and it is very desirable that these should be well understood by the individuals who compose them, and that the advantages arising from them, which are certainly great, should be separated as much as possible from the evils which have unfortunately been too frequently introduced by them. Associations of operatives and of masters may, with advantage, agree upon rules to be observed by both parties in the estimation of the proportionate value of various kinds of work executed in their trade, in order that time may be saved, and disputes between them may be prevented. They may also be most usefully employed in acquiring accurate information of the number of operatives working in the various departments of any Manufacture, their rate of wages, the number of Machines in use among them, and other statistical details. Information of this nature is extremely valuable both for the guidance of the parties who are themselves most interested, and also to enable them, on any application to Government for assistance or for Legislative

Manu-
factures. enactments, to supply those details, without which the propriety of any proposed measure cannot be fitly decided upon. Such details may be collected by men engaged in any trade, at a much smaller expense of time than by persons less acquainted with and less interested in it. Sect. I.

A species of combination occasionally takes place amongst Manufacturers against persons having Patents. These combinations are always injurious to the Public as well as unjust to the inventors. Some years since a gentleman invented a Machine, by which modellings and carvings were cut in mahogany and other fine woods. The Machine resembled, in some measure, the drilling apparatus employed in ornamental lathes; it produced beautiful work at a very moderate expense. But the cabinet-makers met together, and combined against it, and the Patent has consequently never been worked. A similar fate awaited a Machine for cutting veneers by means of a species of knife. In this instance the wood could be cut thinner than by the circular saw, and no waste of it was incurred; but the trade set themselves against it, and after a heavy expense it was given up. Combina-
tion of
masters
against
Patents.

Similar examples of combination seem not to be unfrequent, as appears by the Report of the Committee of the House of Commons on Patents for Inventions, June, 1829. See the evidence of Mr. Holdsworth.

The effects arising from combinations either amongst the master Manufacturers, or amongst the men, are almost always injurious to the Public, and are generally so to the parties themselves. There are, however, numerous instances in which, although the Public suffer by increased price at the moment, they are ultimately gainers from the permanent reduction which results; whilst, on the other hand, the improvements which are often made in Machinery in consequence of a strike amongst the workmen, most frequently do a permanent injury to that particular class which gave rise to them. As the injury to the operatives and to their families is almost always more considerable than that which overtakes their employers, it is of the greatest importance for the comfort and happiness of the former class, that sound views should be entertained by them upon this question. For this purpose a few illustrations of the principle we are maintaining will probably have greater weight than any reasoning of a more general nature, though drawn from admitted principles of Political Economy. Such instances will moreover present the additional advantage of appealing to facts known to many individuals of those classes for whose benefit these reflections are intended. Effect of
combina-
tions

About twenty years ago, the workmen employed in a particular branch of the gun-making trade, struck for an advance of wages. The process on which these men were employed was the making what are called, in the language of the trade, *skelps*.

The *skelp* is a piece or bar of iron, about eighteen inches long, and between two and three broad, thicker at one end than at the other. The barrel of a musket is formed by forging out such pieces to the proper length, and then turning round the edges until they meet, in which state they are welded together.

The persons employed in forging the skelps out of bar-iron struck for an advance of wages, and as their demands were high, they were not immediately complied with. In Instance in
gun-barrels.

Manu-
factures.

the mean time, the superintendent of the establishment directed his attention to the subject, and it occurred to him that if the circumference of the iron rollers between which the bar-iron was rolled were to be made equal in length to two skelps, or to two musket barrels, and if also the groove in which the bar-iron was compressed, instead of being equally deep, were cut gradually deeper from one point in the cylinders to a point exactly opposite, and if it were then gradually diminished in depth until it returned to the first point, then the bar-iron passing between such rollers, instead of being square, would have the form of a series of skelps, each pair of which would be united together at the thicker ends, and these couples would be united to each other by the thinner ends. On making the trial, it was found to succeed perfectly ; a great diminution of human labour took place in that process, and the operatives who had acquired peculiar skill in that particular branch ceased to derive any advantage from it.

Second in-
stance in
gun-
making.

It is somewhat singular that another and a still more remarkable instance of the effect of combination amongst workmen should have occurred but a few years since in the very same trade. The process of welding up the gun-barrels required much skill, and since the termination of the war, the demand for muskets having greatly diminished, the number of operatives in that line was small. This circumstance rendered combination more easy, and upon an occasion when a contract had been entered into for a considerable supply to be delivered at a fixed day, all the men struck for so great an advance of wages as would have caused the completion of the contract to be attended with a very heavy loss. In this difficulty, it occurred to the contractors to make a new trial of a plan for which they had formerly taken out a Patent, but which had never been brought into use. Their process consisted in turning up the skelp into the form of a cylinder, with the edges a little overlapping ; they were then placed in a furnace. When raised to a welding heat, they were taken out, and a triblet, or cylinder of iron, being placed in each, it was passed quickly through a pair of rollers. The effect of this was, that the skelp was drawn out and welded at one heat, and the remainder of the elongation necessary for bringing it to the length of the musket barrel, was performed in a similar manner, but at a lower heat. The operatives who had combined were, of course, no longer wanted, and as the process to which they had been habituated required peculiar skill and considerable experience, they had hitherto been in the habit of earning much higher wages than other workmen of their class. They were, therefore, instead of benefiting themselves by their combination, reduced permanently, in consequence of this improvement in the Art, to a considerably lower rate of wages. On the other hand, the new method of welding was far less injurious to the texture of the iron, in consequence of its being exposed only once, instead of three or four times, to the welding heat, so that the Public derived advantage from the superiority, as well as from the economy of the process. Another advantage has also arisen, for the new process is now applied to the manufacture of iron tubes, which can thus be made at a price which renders them much in demand. Other examples must have presented themselves to those who are familiar with the details of our Manufactories, but these are sufficient to illustrate one of the results of combinations. It would not, however, be fair to push the conclusion deduced

Manu-
factures.

from these examples to its extreme limit. Although it is very apparent that in the two cases which have been stated the effects of combination were permanently injurious to the operative by almost immediately placing him in a lower class (with respect to his daily earnings) than he occupied before; yet they do not prove that *all* such combinations have this effect. It is quite evident that they all have this *tendency*; it is also certain that considerable stimulus must be applied to induce a man to contrive a new process; and that in both these cases, unless the fear of pecuniary loss had acted powerfully, the improvement would not have been made. If, therefore, the workmen had in either case combined for only a small advance of wages, they would, in all probability, have been successful, and the Public would have been deprived for many years of the invention to which these combinations gave rise. The consequence of combination, then, has been to the workmen who combined, reduction of wages; to the Public, reduction of price; and to the Manufacturer, increased sale of his commodity resulting from that diminution of price. It is, however, important to consider the effects of combination in another and less obvious point of view.

The fear of combination amongst the operatives whom he employs will have a tendency to induce the Manufacturer to conceal from his workmen the extent of the orders he may at any time have in hand, and consequently at all times they will know less of the extent of the demand for their labour than they otherwise might. This is injurious to their interests; for instead of foreseeing, by the gradual falling off in the orders, the approach of a time when they must be unemployed, and preparing accordingly, they are liable to much more sudden changes than those to which they would otherwise be subject. As the Manufacturer, when he makes a contract, has no security that a combination may not arise amongst the operatives, which may render that contract a loss instead of a benefit; besides taking precautions to prevent them from becoming acquainted with it, he must also add to the price at which he could otherwise sell the article, some small increase to cover the risk of such an occurrence. If an establishment consist of several branches which can only be carried on jointly, as, for instance, of iron mines, blast furnaces, and a colliery, in which there are distinct classes of operatives, it becomes necessary to keep on hand a larger stock of materials than would be required, if it were certain that no combinations would arise amongst the operatives. Suppose, for instance, the colliers were to strike for an advance of wages, unless there was a stock of coal above ground, the furnaces also must be stopped, and the miners also would be thrown out of employ.

Now the cost of keeping a stock of iron ore or of coals above ground, is just the same as that of keeping unemployed in a drawer its value in money, (except, indeed, that the coal suffers a small deterioration by exposure to air.) The interest of this sum must therefore be considered as the price of an insurance against the risk of combination amongst the workmen; and it must, so far as it goes, increase the price of the Manufactured article, and consequently limit the demand which would otherwise exist for it. But every circumstance which tends to limit the demand, is injurious to the workmen, because the wider the demand the less it is exposed to fluctuation. The effect to

Sect. I.

tages to
operatives.Capital
lying unem-
ployed in
consequence
of fear of
combina-
tion.

Manu-
factures.

which we have alluded is by no means a theoretical conclusion; the proprietors of one establishment in the trade we have mentioned, think it expedient always to keep above ground a supply of coal for six months, which is in that instance equal in value to about 10,000*l*.

ON THE EFFECT OF TAXES AND OF LEGAL RESTRICTIONS UPON MANUFACTURES.

Effects of
taxes

on paper,

on light,

on iron.

Effects of
fixed sizes.

Effects of
removal of a
monopoly.

Whenever Government puts a tax upon any article, the ingenuity of those who make and who use it will immediately become directed to the means of evading as large a part of that tax as they can, and this will often be accomplished in ways that are perfectly fair and legal. An excise duty exists at present of 3*d*.^{*} per pound upon all writing-paper. The effect of this impost is, that much of the paper which is employed is made extremely thin, in order that the weight of a given number of sheets may be as small as possible. Soon after the first imposition of the tax upon windows, which depended upon their number and not upon their size, new built houses began to have fewer windows and of a larger size than before. Staircases derived light from extremely long windows, illuminating three or four flights of stairs. When the tax was increased, and the size of windows charged as single was limited, then still greater care was taken to have as few external windows as possible, and internal lights became frequent. Thus in some instances a tolerable guess might be formed of the age of a house from the nature of its windows.

The effects of duties upon the import of foreign Manufactures are equally curious. A singular instance occurred in the article bar-iron, which is liable to a duty of 140 per cent. *ad valorem*, on introduction into the United States, whilst that upon hardware is 25 per cent. In consequence of this tax, large quantities of malleable iron rails for railroads were imported, and the difference of 125 per cent. in duty more than counterbalanced the expense of fashioning the iron into rails prior to its importation.

The circumstance of restricting the articles produced in a Manufactory to certain sizes, is attended with an economical effect. This arises from the smaller number of different tools required in making them, as well as from less frequent change in the adjustment of those tools. A similar economy prevails in the navy; by having ships divided into a certain number of classes, each of which comprises vessels of the same dimensions, the rigging made for one vessel will fit any of its class.

The effects of the removal of a monopoly are frequently important, and they were perhaps never more remarkable than in the bobbin-net trade, in the years 1824 and 1825. These effects were, however, considerably enhanced by the general rage for speculations which was so prevalent during that singular period. One of the patents of Mr. Heathcote for a bobbin-net machine had expired, whilst another, for an improvement in one part of such Machines, called a *Turn-again*, had yet a few years to run.

* 28*s*. per cwt. for the finer, 21*s*. per cwt. for the coarser papers.

Manu-
factures.

Many licenses had been granted to use the former Patent, which were charged at the rate of about five pounds per annum for each quarter of a yard in width, so that what is termed a six-quarter frame, one which makes bobbin-net a yard and a half wide, paid thirty pounds a year. Infringements of the second Patent having taken place, it was ultimately abandoned in August 1823.

Sect. I.

The bobbin-net Machine occupies little space, and is well adapted for a domestic Manufacture. It had also hitherto yielded very large profit; it is not therefore surprising that on the removal of the monopoly arising from this Patent, a multitude of persons became desirous of embarking in the trade. Those Machines which already existed were principally in the hands of Manufacturers; but a kind of mania seized on persons of all descriptions who could raise a small capital; and accordingly butchers, bakers, small farmers, publicans, gentlemen's servants, and, in some cases, clergymen, were anxious to possess bobbin-net Machines.

Bobbin-net
mania.

Some few Machines were rented; but in most of these cases the workman purchased the Machine he rented, by instalments of from three to six pounds weekly for a six-quarter Machine. Many individuals amongst these classes being unacquainted with the mode of using the Machines so purchased, paid others of more experience for instructing them in their use; fifty or sixty pounds were sometimes given for this instruction. The success of the first speculators at the commencement induced others to follow the example; and the Machine-makers were almost overwhelmed with orders for lace-frames. Such was the desire to procure them, that many persons deposited a large part, or the whole of the price in the hands of the Manufacturers, in order to ensure their having the earliest supply. This, as might naturally be expected, raised the price of wages amongst the operatives employed in Machine-making; and the effect was felt at a considerable distance from Nottingham, which was the centre of this mania. The effect was most remarkable upon the price of the wages of the persons employed in making these Machines.

Rent of
Machines.Rise in
wages.

Smiths not used to *flat filing* coming from distant parts earned from 30s. to 42s. per week. Finishing smiths, accustomed to the work, gained from 3l. to 4l. per week.

The forging smith, if accustomed to his work, gained from 5l. to 6l. per week, and some few earned 10l. per week.

In making what is technically called *insides*, those who were best paid were generally clock and watch-makers, from all the districts round, and who received from 3l. to 4l. per week.

The *setters up*, persons who put the parts of the Machine together, charged 20l. for their assistance; and a six-quarter Machine could be put together in a fortnight or three weeks. Good workmen were thus induced to desert less profitable branches of work in order to supply this extraordinary demand. The masters in other trades found their men leaving them without being aware of the immediate reason; some of the more intelligent traced out the cause, and went from Birmingham to Nottingham, in order to examine into the circumstances which had withdrawn almost all the journeymen clock-makers from their own workshops. It was soon apparent that the men who had

Manu-
factures.

been making clocks at Birmingham at the rate of 25s. a week could earn 2l. by working at lace-frame-making at Nottingham.

Reduction
in price of
bobbin-net.

Diminished
value of
Machines.

On examining the nature of this profitable work, the clock-makers perceived that one part of the bobbin-net Machines, that which held the bobbins, could be easily made in their own workshops. They, therefore, contracted with the Machine-makers, who had already more work ordered than they could execute, to supply the bobbin carriers at a price, which enabled them on their return home to give such increased wages as should retain their own workmen, as well as yield themselves a good profit. Thus an additional facility was afforded to the construction of these bobbin-net Machines. The conclusion was not difficult to be foreseen, the immense supply of bobbin-net thus poured into the market speedily reduced its price. The reduction in price rendered the Machines by which the net was made less valuable, some few of the earliest producers carried on a profitable trade for a short time, but multitudes were disappointed and many ruined. The low price at which the fabric sold, together with its lightness and beauty, combined to extend the sale, and ultimately new improvements in the Machines, rendered the older ones still less valuable.

Productive
power of a
lace-frame.

The bobbin-net trade is at present both extensive and increasing, and as it may probably at some future day claim a larger portion of public attention, it will be interesting briefly to describe its present state.

A lace-frame at the present day on the most improved principle manufacturing a piece of net two yards wide, when worked night and day, will produce 620 racks per week. A rack is 240 holes, and as in the Machine to which we refer three racks are equal in length to one yard, it will produce 21,493 square yards of bobbin-net annually. Three men keep this Machine constantly working, and they were paid by piece-work in 1830 about 25s. each. Two boys, working only in the day-time, will prepare the bobbins for this Machine; these latter are paid from 2s. to 4s. per week according to their skill. Forty-six square yards of this net weigh two pounds three ounces, so that each square yard weighs a little more than three-quarters of an ounce.

For a condensed and general view of the present state of this trade we shall avail ourselves of a statement by Mr. William Felkin of Nottingham, entitled *Facts and Calculations illustrative of the present State of the Bobbin-net Trade*, dated September 1831. It appears to have been collected with care, and contains in a single sheet of paper a body of facts of the greatest importance. We cannot omit the opportunity of expressing our hope that the example will be followed by other trades, and that we may by such means possess a body of information equally important to the capitalist and the operative.

The total capital employed in the factories for preparing the cotton, in those for weaving the bobbin-net, and in various processes to which it is subject, is estimated at above 2,000,000l. and the number of persons who receive wages, at above 200,000.

Manu-
factures.

Comparison of the Value of the Raw Material when Imported, with the Value of Manufactured Goods therefrom.

Square yards 23,400,000 annual produce of bobbin-net, of present value of 1,891,875*l.*

"The brown nets which are sold in the Nottingham market, are in part disposed of by the agents of twelve or fifteen of the larger makers, *i. e.* to the amount of about 250,000*l.* a year. The principal part of the remainder, *i. e.* about 1,050,000*l.* a year, is sold by about 200 agents, who take the goods from one warehouse to another for sale. Of course, many of these are of respectable character and competent to the task they undertake, and which from the amount of property just stated as annually passing through their hands, and the agent not usually giving up the name of the purchasers to his principals, is evidently a very responsible one. It is to be regretted, that the confidence of the Machine owners has not in some recent instances been justified by the conduct of those they employed. Long-continued series of forced sales, effected by some agents of bad character and habits, for the purpose of temporarily meeting the claims of those whose goods had been placed in their hands for sale, have very seriously and permanently affected the general prices of the market, eventually caused losses to the Machine owners, and reflected unmerited discredit on those of the commission agents who conduct their sales with business-like precision and integrity. Now that the smaller Machine owners' property in Machinery is become almost or entirely valueless, and the profits of all are reduced to what at least in this trade is an unusually low rate, it is surely very desirable to guard, by the exercise of increased caution, against frauds or irregularities, calculated so materially to prejudice both those who make bobbin-net and those who hold stocks of it, and the temptations to which are great in proportion to the ease and secrecy by which they may be effected and for a time carried on.

"Of this production, about half is exported in the unembroidered state, and in the white principally; yet a large quantity is sent in the unbleached state, and is embroidered abroad, and much is figured in the white on the Continent. So that it is probable that as much is figured abroad as at home, and this principally on account of wages being lower there than here, notwithstanding the low rate of embroiderers' earnings in this Country. This foreign embroidery is chiefly done in Belgium, Saxony, and until recently, Poland. The exports of bobbin-net are in great part to Hamburgh, for sale at home and at Leipzig and Frankfort fairs, Antwerp, and the rest of Belgium; to France, by contraband; Italy, and North and South America. Though a very suitable article, yet the quantity sent Eastward of the Cape of Good Hope has hitherto been too trifling for notice. Three-eighths of the whole production is sold unembroidered at home. The remaining one-eighth is embroidered in this Country, and increases the ultimate value as under, *viz.*

Embroidery on power net increases value	131,840 <i>l.</i> , and is ultimately worth	553,715 <i>l.</i>
Ditto on hand	1,205,860	2,583,985
Ditto on fancy	78,750	105,000
Ditto on silk	109,375	175,000

Total embroidery wages and profit 1,525,825*l.* Ultimate total value. . 3,417,700*l.*

"From this it appears, that in the operations of this trade, which had no existence twenty years ago, 120,000*l.* original cost of cotton, becomes when Manufactured, of the ultimate value of 3,242,700*l.* sterling.

"There are about seventy houses engaged chiefly in embroidering goods, and about seventy houses engaged

Manu-
factures.

" in the preparation and sale of plain goods principally. The *cash* paid to small owners, for the purchase of hand
 " nets, about equals the amount of capital created by the credit given in this market by power net Manufac-
 " turers.

Sect. I.

" As to weekly wages paid, I hazard the following as the judgment of those conversant with the respective
 " branches, viz.

" In fine spinning and doubling: adults, 25s.; children, 7s.; work twelve hours per day.

" In bobbin-net making: men working Machines, 18s.; apprentices, youths of fifteen or more, 10s.; by power,
 " fifteen hours; by hand, eight to twelve hours, according to width.

" In mending: children, 4s.; women, 8s.; work nine to fourteen hours, *ad libitum*.

" In winding, threading, &c.: children and young women, 5s.; irregular work, according to the progress of
 " Machines.

" In embroidery: children, seven years old and upwards, 1s. to 3s.; work ten to twelve hours; women, if
 " regularly at work, 5s. to 7s. 6d.; twelve to fourteen hours.

" As an example of the effect of the wages of lace embroidery, &c. it may be observed, it is often the case
 " that a stocking weaver in a country village will earn only 7s. a week, and his wife and children 7s. to 14s.
 " more at the embroidery frame."

The principal part of the hand Machines are worked in shops, forming part of, or
 attached to private houses. The subjoined list will show the kinds of Machinery em-
 ployed, and classes of persons to whom it belongs.

Mansfield	85
Tiverton	220
Barnstable	180
Chard	190
Isle of Wight	80
In sundry other places	990
	4500

"Of the above owners, 1000 work in their own Machines, and enter into the class of journeymen as well as masters in operating on the rate of wages. If they reduce the price of their goods in the market, they reduce their own wages first, and, of course, eventually the rate of wages throughout the trade.—It is a very lamentable fact, that one-half, or more, of the 1100 persons specified in the list as owning one, two, and three Machines, have been compelled to mortgage their Machines for more than their worth in the market, and are in many cases totally insolvent. This has chiefly arisen from the fall in prices of nets beyond the reduction in prices of cotton and wages. This class of persons having become indebted to the cotton Merchant, have been compelled to pay a comparatively excessive price for the thread they have used, and to sell their goods at the lowest prices of the market. Besides, their Machines are principally narrow and making short pieces, while the absurd system of bleaching at so much a piece goods of all lengths and widths, and dressing at so much all widths, has caused the new Machines to be all wide and capable of producing long pieces, and of course to the serious disadvantage, if not utter ruin, of the small owner of narrow Machines.

"It has been observed above, that wages have been reduced, say 25 per cent. in the last two years, or from 24s. to 18s. a week. Machines have increased in the same time one-eighth in number, or from 4000 to 4500, and one-sixth in capacity of production. It is deserving the serious notice of all proprietors of existing Machines, that Machines are now introducing into the trade of such power of production as must still more than ever depreciate (in the absence of an immensely increased demand) the value of their property, have a direct tendency to sink the small owners into journeymen, and either greatly increase the labour, or depreciate the workman's wages. It is a curious fact, as illustrative of the progress of Machinery, that there are bobbin-net Machines, which, being worked by three men, six hours each or eighteen hours per day, are turning off 20,000 square yards of good net per annum. Now it is not to be fairly denied, that such Machines being multiplied to some extent, must, with only the actual demand, lower even the present trifling value of the 1600 or 1700 narrow hand Machines, one half or more, and reduce the rate of wages of those who work in them one-third, and that of the remaining hand Machine workmen at least one-fourth; or, which is the same thing, compel them to increase their labour in the same proportion."

From this abstract we may form some judgment of the importance of the bobbin-net trade. But the extent to which it bids fair to be carried when the Eastern markets shall be more open to our industry, may be conjectured from the fact which Mr. Felkin states,—that "We can export a durable and elegant article in cotton bobbin-net at 4d.

factures.

“per square yard, proper for certain useful and ornamental purposes, as curtains, &c. ; Sect. 1.
 “and another article used for many purposes in female dress at 6d. the square yard.”

Patents.

In order to encourage the importation, the improvement, or the invention of Machines and discoveries relating to Manufactures, it has been the practice in many Countries to grant to the first introducers an exclusive privilege for a term of years. Such monopolies are termed Patents, and are granted on the payment of certain fees for different periods from five to twenty years.

Their ex-
pense.

The following Table, compiled from the Report of the Committee of the House of Commons on Patents, 1829, shows the Expense and Duration of Patents in various Countries.

	Expense.	Term of Years.	Number granted in six years, end- ing in 1826.— (Rep. p. 243.)
	£		
England.....	120	14	914

Spain..... Inventor..	20 9s. 4d.	15	
Improver ..	12 5s. 7d.	10	
Importer..	10 4s. 8d.	6	

It is clearly of importance to preserve to each inventor the sole use of his invention, until he shall have been amply repaid for the risk and expense to which he has been exposed, as well as for the talent he has exerted. But the degrees of merit are so numerous, and the difficulties of legislating upon the subject are so great, that it has been found practically to be almost impossible to frame a law which shall not be open to the most serious objections.

The difficulty of defending an English Patent in any judicial trial has been found to be very great, and the number of instances on record in which the defence has succeeded are comparatively few. This circumstance has induced some Manufacturers no longer to regard a Patent as a privilege by which a monopoly price may be secured; but they sell the Patent article at such a price as will merely produce the ordinary

* The expense of a Patent in Spain is stated in the Report to be respectively 2000, 1200, and 1000 reals. If these are reals of *Vellon*, in which accounts are usually kept at Madrid, the above sums are correct; but if they are reals of *Plate*, then the above sums ought to be nearly doubled.

Manu-
factures. profits of capital, and thus secure to themselves the fabrication of it, because no competitors can derive a profit from invading a Patent so exercised. Sect. I.

Amongst the restrictions intended for the general benefit of our Manufacturers, there existed one by which workmen were forbidden to go out of the Country. A law so completely at variance with every principle of liberty ought never to have been enacted. It was not, however, until experience had convinced the Legislature of its inefficiency that it was repealed. When the intercourse between England and the Continent became extensive, it was soon found that it was impossible to discover the various disguises which could be assumed, and the effect of the law was rather to deter by the fear of punishment the workmen who had left the Country from returning, than to prevent their disposition to migrate.

ON THE EXPORTATION OF MACHINERY.

Not only were workmen prohibited by Act of Parliament from transporting themselves to a Country in which their industry would produce for them higher wages, but it was forbidden to export the greater part of the Machinery which they were employed to make at home. The reason of this prohibition was, that foreigners might not avail themselves of our improved Machinery, and thus compete with our Manufacturers. It was, in fact, a sacrifice of the interests of one class of persons, the makers of Machinery, for that of another class, those who use it. Now, independently of the impolicy of interfering unnecessarily between them, it may be observed, that the first class, or the makers of Machinery, are, as a body, far more intelligent than those who only use it; and although, at present, they are not nearly so numerous, yet, if the prohibition which cramps their ingenuity were removed, there appears good reason to believe that their number would be greatly increased, and that it might, in time, surpass that of those who use Machinery.

The advocates of such prohibitions seem to rely greatly upon the possibility of preventing the knowledge of new contrivances being conveyed from one Country to another, and they also appear to take too limited a view of the possible, and even probable, improvements in Mechanics. For the purpose of examining the question, we will consider the case of two Manufacturers of the same article, one situated in a Country in which labour is very cheap, the Machinery very bad, and the modes of transport slow and expensive; the other engaged in Manufacturing in a Country in which the price of labour is very high, the Machinery very excellent, and the means of transport expeditious and economical. Let them both send their produce to the same market, and let each receive such a price as shall give to him the profit ordinarily produced by capital in his own Country. It is almost certain that in such circumstances the first improvement in Machinery will occur in the Country which is most advanced in civilization, because even admitting that the ingenuity to contrive were the same in the two Countries, the means of execution are very different. The effect of any improved Machinery in the rich Country will be perceived in the common market by a small fall in the price of the Manufactured article. This will be the first intimation to the Manufacturer of the poor

Comparative view

poor Country.

Manu-
factures.

Sect. I.

Country, who will endeavour to meet this diminution in the selling price of his article by increased industry and economy in his factory, but he will soon find that this remedy is temporary, and the market-price is still falling. This will induce him to examine the rival fabric, in order to detect by its structure any improved mode of making it. If, as would most usually happen, he should be unsuccessful in this attempt, he will be forced to endeavour to contrive some improvement in his Machinery, or to acquire information respecting that which has taken place in the factories of the rich Country. Perhaps after an ineffectual attempt to attain by letters the information he requires, he sets out to visit the factories of his rivals. To a foreigner and rival Manufacturer such establishments are not easily accessible, and the more recent the improvement, the less likely he will be to gain access to them. His next step will be to acquire a knowledge of them from the workmen employed in using or making the Machines. Without Drawings or an examination of the Machines themselves, this process will be a slow and tedious one, and he will be liable after all to be deceived by artful and designing workmen, and be exposed to many chances of failure. But suppose he returns to his own Country with perfect Drawings and instructions he must then begin to construct his improved Machines: these cannot be executed by him either so cheaply or so well as they are in the richer Country; but after the lapse of some time, let us suppose them to be in working order.

Let us now consider what will have occurred to the Manufacturer in the rich Country, even supposing that during the whole of this time he has made only one step. He will, in the first instance, have realized a profit by supplying the home market at the usual price with an article which it costs him less to produce; he will then reduce the price both in the home and foreign market in order to produce a more extended sale. It is in this stage that the Manufacturer in the poor Country first feels the effect of the competition; and if we suppose that from the first application of the new improvement in the rich Country, and the commencement of its employment in the poor Country only two or three years elapse, yet will the Manufacturer who contrived the improvement have realized so large a portion of the outlay which it rendered necessary, that he will now be in a state to make a much greater reduction in the price of his produce, and thus render the gains of his rivals quite inferior to those which his own ingenuity had produced for himself.

It is contended that by admitting the exportation of Machinery, foreign Manufacturers will be supplied with Machines equal to our own. Now the first answer which presents itself is supplied by almost the whole of the present Essay, *viz. That in order to succeed in a Manufacture, it is necessary not merely to possess good Machinery, but that the domestic economy of the factory should be most carefully regulated.*

The truth, as well as the importance of this principle is so well established in the Report of a Committee of the House of Commons "On the Export of Tools and Machinery," that we shall avail ourselves of the opinions and evidence there stated before we offer those additional observations which have occurred to our own experience.

Manu-
fact-
res.

Sect. I.

Report of
House of
Commons
on Export
of Tools
and Ma-
chinery.

"Supposing, indeed, that the same Machinery which is used in England could be obtained on the Continent, it is the opinion of some of the most intelligent of the witnesses that the want of arrangement in foreign Manufactories, of division of labour in their work, of skill and perseverance in their workmen, and of enterprise in the masters, together with the comparatively low estimation in which the master Manufacturers are held on the Continent, and with the comparative want of capital, and of many other advantageous circumstances detailed in the evidence, would prevent foreigners from interfering in any great degree by competition with our principal Manufacturers; on which subject the Committee submit the following evidence as worthy the attention of the House:

'I would ask whether, upon the whole, you consider any danger likely to arise to our Manufactures from competition, even if the French were supplied with Machinery equally good and cheap as our own?—They will always be behind us until their general habits approximate to ours; and they must be behind us for many reasons that I have before given.

'Why must they be behind us?—One other reason is, that a cotton Manufacturer who left Manchester seven years ago, would be driven out of the market by the men who are now living in it, provided his knowledge had not kept pace with those who have been during that time constantly profiting by the progressive improvements that have taken place in that period; this progressive knowledge and experience is our great power and advantage.'

"It should also be observed, that the constant, nay almost daily, improvements which take place in our Machinery itself, as well as in the mode of its application, require that all those means and advantages alluded to above, should be in constant operation; and that, in the opinion of several of the witnesses, although Europe were possessed of every tool now used in the United Kingdom, along with the assistance of English artisans, which she may have in any number, yet from the natural and acquired advantages possessed by this Country, the Manufacturers of the United Kingdom would for Ages continue to retain the superiority they now enjoy. It is indeed the opinion of many, that if the exportation of Machinery were permitted, the exportation would often consist of those Tools and Machines which, although already superseded by new inventions, still continue to be employed from want of opportunity to get rid of them, to the detriment, in many instances, of the Trade and Manufactures of the Country; and it is matter worthy of consideration, and fully borne out by the evidence, that by such increased foreign demand for Machinery, and the ingenuity and skill of our workmen would have greater scope, and that, important as the improvements in Machinery have lately been, they might, under such circumstances, be fairly expected to increase to a degree beyond all precedent.

"The many important facilities for the construction of Machines and the Manufacturing of commodities which we possess, are enjoyed by no other Country, nor is it likely that any Country can enjoy them to an equal extent for an indefinite period. It is admitted by every one that our skill is unrivalled; the industry and power of our people unequalled; their ingenuity, as displayed in the continual improvement of Machinery and production of commodities, without parallel, and apparently without limit. The freedom which, under our Government, every man has to use his capital, his labour, and his talents, in the manner most conducive to his interests, are inestimable advantages; canals are cut, and rail-roads constructed, by the voluntary association of persons whose local knowledge enables them to place them in the most desirable situations; and these great advantages cannot exist under less free Governments. These circumstances, when taken together, give such a decided superiority to our people, that no injurious rivalry either in the construction of Machinery or the Manufacture of commodities can reasonably be anticipated."

It would appear, also, that there are circumstances which show that the immediate exportation of improved Machinery is not quite so certain, and that the powerful principle of self-interest will urge the makers of Machinery to push its extension in a different direction.

When a great maker of Machinery has contrived a new Machine for any particular

Manu-
factures.
Makers of
Machines
sometimes
invent im-
provements.

Sect. I.

process, or has made some great improvement on those in common use, to whom will he naturally apply for the purpose of selling his new Machines? Undoubtedly, in by far the majority of cases, he will communicate the circumstance to his nearest and best customers, those to whom he has immediate and personal access, and whose capability to fulfil any contract is best known to him. He will communicate with them, and offer to take their orders for the new Machine, nor will he think of writing to inform foreign customers so long as he finds the whole force of his establishment insufficient to supply the home demand. Thus then the Machine-maker is himself interested in giving the first advantage of any new improvement to his own Countrymen.

The class of operatives who make Machinery possess much more skill, and are paid much more highly than that class who merely use it, and if a free exportation of Machinery were allowed, this higher and more valuable class would undoubtedly be greatly increased. For, notwithstanding the high price of wages, there is no Country in which Machinery can at this moment be made either so well or so cheaply as in England. We might, therefore, supply the whole World with Machinery, at an evident advantage both to ourselves and our customers. In Manchester, and the districts round about, thirty thousand men are employed in Manufacturing the Machinery which gives employment in the same district to hundreds of thousands of operatives. The time can yet be remembered by some, when the number of the whole population engaged in the cotton-trade of that district did not exceed that of those now employed in making the Machines the present population use. Hence, then, if England should ever become a great exporter of Machinery, she would necessarily contain a large class of workmen to whom skill would be indispensable, and, consequently, to whom high wages would be paid; and her Manufacturers would be fewer in numbers, but they would undoubtedly have the advantage of being the first to derive profit from improved Machinery. Under such circumstances any diminution of demand in Machinery would, in the first instance, be felt by a class much better able to meet it, than the class which now suffers upon every check in the consumption of our Manufactured goods; and the resulting misery would therefore assume a mitigated character.

Objections
to exporta-
tion.

The objections to which the exportation of Machinery is liable, arise from the anticipation that the demand of the World is not sufficient to give occupation to a large proportion of the operatives of one Country more favourably circumstanced than all others for exercising that trade. It is also feared that when other Countries have purchased our Machines, they will cease to demand new ones. On the first of these objections it may be observed that, in point of fact, we have not at present sufficient workmen in that line of employment to supply much beyond the home demand for Machinery, and that the demand would increase by degrees, and workmen be produced in consequence of it. To the other objection, the statement we have given of the usual progress in the improvements of the Machinery employed in any kind of Manufacture, and the average duration of it not arising from wear and tear, but from its being superseded, is a complete reply.

If our customers did not adopt the new Machinery contrived by us as soon as they

Manu-
factures.

Sect. I.

could procure it, then our own Manufacturers would extend their establishments, and undersell their rivals in their own markets. It may also be urged, that in each kind of Machinery a maximum of perfection may be imagined beyond which it is impossible to advance. The last advances are usually the smallest when compared with those which precede them; but it should be observed, that they generally occur when the number of Machines in employment is already large, and consequently their effects upon the power of producing are very considerable. Although it should be admitted that any individual species of Machinery may arrive after a long period at a degree of perfection which would render further improvement nearly hopeless, yet it is impossible to suppose that this can be the case with all kinds of Mechanism. The limit of improvement is rarely approached, except in extensive branches of National Manufactures, and the number of such branches is even at present very small.

The productions of Nature, varied and numerous as they are, may each, in some future day, become the basis of extensive Manufactures, and give life, employment, and wealth to millions of Human beings. But the crude treasures perpetually exposed before our eyes contain within them other and more valuable principles. All these, in their innumerable combinations, which Ages of labour and research can never exhaust, may be destined to furnish, in perpetual succession, the sources of our wealth and of our happiness. Science and Knowledge are subject, in their extension and increase, to laws quite opposite to those which regulate the Material World; unlike the laws of Molecular Attraction, which cease at sensible distances, or that of Gravity, which decreases rapidly with the increasing distance from the point of its origin, the further we advance from the origin of our Knowledge, the larger it becomes, and the greater power it bestows upon its cultivators to add new fields to its dominions. Yet does this continually and rapidly increasing power, instead of giving us any reason to anticipate the exhaustion of so fertile a field, place us at each advance on some higher eminence, from which the mind contemplates the past, and feels irresistibly convinced that the whole already gained bears a constantly diminishing ratio to the still more rapidly expanding horizon of our Knowledge. But if the knowledge of the Chemical and Physical properties of the bodies which surround us, as well as that of the less tangible elements, Light, Electricity, and Heat, which mysteriously modify or change their combinations, all concur to convince us of the same fact; we must remember that another and a higher Science, itself still more boundless, is also advancing with a Giant's stride, and having grasped the mightier masses of the Universe, and reduced their wanderings to laws, has given to us in its own condensed language expressions, which are to the past as History, to the future as Prophecy. It is the same Science which is now preparing its fetters for the minutest atoms which Nature has created: already it has nearly chained the ethereal fluid, and bound in one harmonious system all the intricate and splendid phenomena of Light. It is the Science of *Calculation*, which becomes continually more necessary at each step of our progress, and which must ultimately govern the whole of the applications of Science to the Arts of life.

nic districts.

increasing field of Human Knowledge, that the weak arm of man may want the physical force requisite to render that knowledge available. The experience of the past has stamped with the indelible character of truth the maxim that "*Knowledge is Power.*" It not merely gives to its votaries control over the mental faculties of their species, but it is the generator of physical force. The discovery of the expansive power of steam, its condensation, and the doctrine of latent heat, has already added to the population of this small island millions of hands. But the source of this power is not without limit, and the coal-mines of the World may ultimately be exhausted. Without adverting to the theory that new formations of that mineral are now depositing under the sea, at the estuaries of some of our larger rivers; without anticipating the application of other fluids requiring a less supply of caloric than water;—we may remark that the sea itself offers a perennial source of power hitherto almost unapplied. The tides, twice in each day, raise a vast mass of water, which might be made available for driving Machinery. But supposing heat still to remain necessary when the exhausted state of our coal-fields renders it expensive. Long before that period arrives, other methods will probably have been invented for producing it. In some districts there are springs of hot water, which have flowed for centuries unchanged in temperature. In many parts of the island of Ischia, by deepening the sources of the hot springs but a few feet, the water boils, and there can be little doubt that, by boring a short distance, steam of high pressure would issue from the crifice: here then is a natural source of heat, one which is extensively spread over the Globe, since it occurs near all active volcanoes. Whether the abstraction of heat on a large scale might not have the effect of diminishing the frequency or the intensity of their eruptions, and whether such Countries may not ultimately be destined to become the great centres of the Manufactures of the World, must be decided by time and circumstances.

CONCLUSION.

Having now completed the view we proposed to take of the general principles which regulate the successful application of Mechanical Science to great establishments for the production of Manufactured goods, it remains for us to suggest a few inquiries, and to offer a few observations to those whom an enlightened curiosity may lead to examine the factories of this or of other Countries.

The first remark applies to almost all inquiries, *viz.* that *it is important to commit to writing, all information as soon as possible after it is received, especially when numbers are concerned.*

Necessity of
writing
down infor-
mation on
the spot.

It is frequently impossible to do this when visiting an establishment, and where not even the slightest jealousy exists; the mere act of writing information as it is communicated orally, is a great interruption to the examination of Machinery. In such cases, therefore, it is advisable to have prepared beforehand the questions to be asked, and to leave blanks for the answers, which may be quickly inserted, as they are in a multitude of cases merely numbers. Those who have not tried this plan will be surprised at the quantity of information which may be acquired through its means, even by a short examination.

Manu-
factures.

Sect. I

Each Manufacture requires its own list of questions, which will be better drawn up after the first visit. The following outline, which is very generally applicable, may suffice for an illustration; and to save time it may be convenient to have it printed, and to bind up in the form of a pocket-book, a hundred copies of the skeleton forms for processes, with about twenty of the general inquiries.

GENERAL INQUIRIES.

Outlines of a Description of any of the Mechanical Arts ought to contain information on the following points.

Brief sketch of its history, particularly the date of its invention and its introduction into England.

Short reference to the previous states through which the material employed has passed; the places whence it is procured; the price of a given quantity.

The various processes must now be described successively according to the plan (B); after which the following information should be given:

Are various kinds of the same article made in one establishment, or at different ones, and are there differences in the processes?

To what defects are the goods liable?

What substitutes or adulterations are used?

What waste is allowed by the master?

What tests are there of the goodness of the Manufactured article?

The weight of a given quantity, or number, and a comparison with that of the raw material.

The wholesale price at the Manufactory, £. s. d. per

The usual retail price, £. s. d. per

Who provide tools? Master, or Men. Who repair tools? Master, or Men.

What is the expense of the Machinery?

What is the annual wear and tear, and what its duration?

Is there any particular trade for making it? Where?

Is it made and repaired at the Manufactory?

In any Manufactory visited, state the number () of processes, and of persons employed in each process, and the quantity of Manufactured produce.

What quantity is made annually in Great Britain?

Is the capital invested in Manufactories large or small?

Mention the principal seats of this Manufacture in England; and if it flourishes much abroad, the places where it is established should be mentioned.

The duty, excise, or bounty, if any, should be stated; and any alterations in past years; and also the amount exported or imported for a series of years.

Whether the same article, but of superior or inferior make, is imported.

Does the Manufacturer export, or sell, to a middle-man, who supplies the merchant?

To what Countries is it chiefly sent—and in what goods are the returns made?

Each process requires a separate skeleton, and the following outline will be sufficient for many different Manufactories.

Manu-
factures. Process () Manufacture () Place () Name () Sect. I.
date 183

The mode of executing it, with sketches of the tools or Machine if necessary.

The number of persons necessary to attend the Machine.

Are the operatives men, () women, () or children? () If mixed, what are the proportions?

What is the pay of each? (s. d.) (s. d.) (s. d.) per

What number () of hours do they work per day?

Is it usual, or necessary, to work night and day without stopping?

Is the labour performed by piece or by day-work?

Who provide tools? Master, Men. Who repair tools? Master, Men.

What degree of skill is required, and how many years' () apprenticeship?

The number of times () the operation is repeated per day or per hour.

The number of failures () in a thousand.

Whether the workman or the master loses by the broken ones?

What is done with the broken ones?

If the same process is repeated several times, state the diminution or increase of measure, and the loss, if any, at each time.

Use of the
skeletons.

In using this skeleton, the answers to the questions are in some cases printed as, Who repair the tools? Masters, Men; in order that the proper answer may be underlined with a pencil. In filling up the answers which require numbers, some care should be taken; for instance, if the observer stands with his watch in his hand before a person heading a pin the workman will almost certainly increase his speed, and the estimate will be too large. A much better average will result from inquiring what quantity is considered a fair day's work. When this cannot be ascertained, the number of operations performed in a given time may frequently be ascertained, when the workman is quite unconscious that any person is observing him. Thus the sound made by the motion of a loom may enable the observer to count the number of strokes per minute, even though he is outside the building in which it is contained.

It frequently happens that in a series of answers to such questions, there are some which, although given directly, may also be deduced by a short calculation from others that are given or known, and advantage should always be taken of these verifications in order to confirm the accuracy of the statements, or in case they are discordant, to correct the apparent anomalies. In putting lists of questions into the hands of a person undertaking to give information upon any subject, it is in some cases desirable to have an estimate of the soundness of his judgment. The questions can frequently be so shaped that some of them may indirectly depend on others, and one or two may be inserted whose answers can be obtained by other methods; nor is this process without its advantages in enabling us to determine the value of our own judgment. The habit of forming an estimate of the magnitude or frequency of any object immediately previous to our applying to it measure or number, tends materially to fix our attention and to improve our judgment.

MANUFACTURES.

PART I.

MACHINERY.

**Manufac-
tures.** (1.) IN order to follow out the plan sketched in the preceding Introductory Chapter, it is necessary, before we proceed to describe the processes of different Manufactories, that we should explain and illustrate the fundamental principles of the Machines by which these processes are conducted, and also such simple Machines as are of common application and use; for it is obvious that unless these are properly understood in their simple forms, it will be impossible to comprehend their operation in the complicated and combined forms in which they are employed in the various Manufactories we shall have to describe.

**Definition
of a Ma-
chine.** Amongst the Ancients, the term Machine was applied to every tool or instrument employed in the performance of any work; with us it is more restricted, but it is still of uncertain application; the best definition of Machine, as it relates to manufacturing processes, seems to be, that it is a construction combining different mechanical powers with a view to the production of some ulterior and definite object, and is, except so far as custom has in a few cases made a sort of distinction, synonymous with Engine. The English, for instance, always say Steam-engine, but the French call this a Machine, *Machine à vapeur*. In fact, there are a number of cases in which Machine or Engine is used with perfect indifference; as for example, Planing Engine or Planing Machine, Boring Engine or Boring Machine, Dividing Engine or Dividing Machine, &c. The same definition may therefore be applied both to Engine and to Machine, the application of one term or the other being rather a matter of custom than expressive of an intrinsic difference, in those cases where the one or the other is employed.

The object intended to be effected in every Machine is to transmit a certain power or force applied on one part, called the applied point, to another part, called the working point, in order there to produce some mechanical operation. We shall first, therefore, inquire into the nature of those forces or powers by which motion is communicated, generally designated *motive forces*; secondly, of those which, from the imperfect nature of Machinery, have a tendency to counteract and impede this motion, called therefore *retarding forces*; and lastly, of those which are introduced to modify and regulate the motion resulting from the variable difference of the two former, and which may therefore be termed *regulating forces*.

I. OF MOTIVE FORCES.

**First
movers.** *Motive forces or first movers may be divided into the following five classes:*

1. The muscular power of men.
2. The muscular power of horses and other animals.
3. The power or force of the wind.
4. The weight and moving force of water.
5. The expansive force and rapid condensation of steam.

(2.) In order to form a comparison between the effects **Machinery** produceable from these different sources of motion, it is at least convenient, if not necessary, to have one common **Dynamic** standard of reference, or one definite dynamic unit. In **unit.** this Country we employ what is called a *horse-power*, and it was perhaps at first intended to represent the medium effort of a horse. Several recent experiments, however, some of which were attended by the writer of this Essay, prove most distinctly that the nominal horse-power very far exceeds the actual power of the strongest horse, to continue working day by day, and much more the medium power of horses in general. This however is immaterial, so that the amount of what **Horse-
power.** is called a horse-power is properly understood. The horse-power, then, may be defined to be a force, from whatever source it arises, which is competent to raise 33,000 pounds one foot high in a minute, or more precisely, a force such that the weight raised by it in a minute, multiplied by the number of feet to which it is raised, shall produce the above number, 33,000, abstracting from every kind of resistance but the load itself. This distinction leads us to another consideration, namely, the maximum power of a horse for useful mechanical effect. When we state that 33,000 pounds raised a foot high in a minute is a horse-power, it is obvious that to raise this power unaided by Machinery is inconsistent with the muscular power of the animal; on the other hand, to raise 1 pound to the height of 33,000 feet is inconsistent with his speed. The number 33,000 must therefore be divided into two factors, one representing the weight in pounds and the other the number of feet per minute he is able to raise it, so that the product of the two may bring out the number required, and such that both the weight and speed may be best adapted to the power of the animal.

It has been ascertained from a number of well-directed experiments, that the speed at which a horse can move, so as to produce the maximum mechanical effect, is $2\frac{1}{2}$ English miles per hour, or 220 feet per minute; at which rate, taking the horse-power at what is above stated, he will constantly oppose a resistance or weight of 150 pounds; but from observations made on the resistance of canal boats, which are frequently drawn at about the rate of $2\frac{1}{2}$ miles an hour, it does not appear that a horse can be advantageously opposed to more than 100 pounds; and moreover, that being opposed to that resistance and moving with the velocity of $2\frac{1}{2}$ miles per hour, or 220 feet per minute, or $3\frac{2}{3}$ feet per second, the best effect is produced. It appears, therefore, that the actual medium power of a horse does not exceed 22,000 pounds a foot high in a minute.

(3.) In order to show the great economy in the employment of horses by adjusting the speed and weight to the nature of the animal's physical powers, we may take the case of our quick day-coaches; in these it is well known that proprietors consider it necessary to employ a horse

Manufac-
tures.

Horse-la-
bour in day-
coaches.

per mile, to horse the coach to and fro—that is, for a distance of 80 miles, eighty horses are employed or provided; for 100 miles one hundred horses; and so on; so that actually, taking rests into account, each horse travels but 8 miles per day. Again, the mean weight of such coaches, including passengers and luggage, is estimated at about 4200 pounds, and the resistance of our best turnpike roads is about one-thirtieth of the weight drawn, (Leslie's *Elements*, p. 253.) so that the force requisite to overcome the resistance of such a coach is 140 pounds; to effect this we have four horses; consequently, each horse has to exert a force of 35 pounds. We may therefore take 35 pounds $\times$ 8 miles = 280, as the measure of a horse's power for the day, when travelling at the rate of 10 miles per hour, whereas by reducing the speed to $2\frac{1}{2}$ miles per hour, the horse will be able to draw 100 pounds, and to continue his labours for 8 hours, or for 20 miles. We have therefore for a measure of his day's work at this rate 100 pounds $\times$ 20 miles = 2000, which is more than 7 times the mechanical effect produced at 10 miles per hour. In the case we here have taken of a quick stage-coach, this loss of power for the sake of gaining speed is unavoidable, but in a horse-mill, where we have it in our power to choose the speed, the advantage of attending to the capability of the animal is sufficiently obvious. For more on this subject, see the Chapter on RAILWAYS.

Comparison
of the nomi-
nal and ac-
tual horse-
power.

Having made these few remarks on the dynamic unit selected by English engineers, and on the excess of that unit beyond the unit it professes to represent, we may point out how much an engine denominated by horse-powers, when worked by steam, water, &c. exceeds the number of horses that must be employed to perform the same work in 24 hours, working night and day. To take as an example, a 10-horse-power engine, we have seen that the artificial horse-power here taken is expressed by 33,000; that the actual medium power of a horse must not be taken, when working to the best advantage, at more than 22,000; that the former will continue working twenty-four hours, and the latter only eight hours, and we shall then have the following numbers to express the relative effects, viz. for the engine 33,000 pounds $\times$ 24 hours $\times$ 10 horses = 7,920,000, and in the other case where horses are actually employed, 22,000 pounds $\times$ 8 hours $\times$ 10 horses = 1,760,000; whence as 176 : 792 :: 10 : 45. Consequently, if a steam-engine of 10 horses nominal power were kept at work day and night, it would require 45 horses to perform the same work in the same time; and making every allowance for stoppages, oiling, packing, &c. every nominal horse-power in a steam-engine is equivalent to four horses when working night and day, to two horses when working twelve hours per day, and equal to $1\frac{1}{2}$ horse when working eight hours per day. This will be an important consideration when we shall have to consider economy in the due selection of first movers.

In thus defining and illustrating the dynamic unit, or horse-power, we have been led to enter upon the amount of an actual horse-power, whereas to have proceeded regularly, we ought to have spoken first of the power of men; the transposition was however in some measure unavoidable.

Mechanical
power of
men.

(4.) *Of the power of men as first movers.*—Experiments have been made by Desaguliers, Smeaton, and others to determine the power of a man when employed as a mere source of mechanical action. Of course there will be a great variety of results in such experiments, because

men differ much from each other, not only in their absolute muscular power, but in their capability of exerting it in different ways. One man at a winch may be capable of an exertion far greater than another; but set these same two men to row in a boat, and the case may be reversed. Again, where the distance passed over forms a part of the effort, as in the case of men employed to remove sand or soil from one place to another, we shall find men excelling here who have but inferior power in either of the cases above named. Consequently we can hardly expect any very definite measure of a man's strength when considered as a mere source of mechanical power. It has, however, been decided by Smeaton, from a mean of several comparisons, that five good English labourers are about equivalent to the power of one horse. This must, however, be understood as the actual and not the nominal unit, therefore the power of a man may be stated to be such as is capable of raising 4400 pounds one foot high in a minute, or 30 pounds to the height of 146 feet in a minute. The writer of this Essay is aware that this is less than is sometimes stated to express the power of a man, but the experiments of Smeaton having fixed the ratio between the actual power of a man and horse at 1 to 5, and the power of the horse having been found to amount but to 22,000 pounds, that of the man will be no more than is above stated. Indeed, Smeaton himself, in one of his results, makes it only 3700 pounds, but this is making six men equivalent to one horse. It is, however, given by Emerson as equivalent to 6300 pounds, that is to raising 30 pounds 210 feet high in a minute, but this is certainly erroneous; much, however, will depend upon the nature of the exertion, and whether the man is accustomed to exert his strength in the manner required.

(5.) It is almost impossible to employ a horse as a first mover without locomotion, that is without causing him to pass over a certain space, and that space we have seen is 20 miles in a day, in order that he may produce the greatest effect; now the mere exertion of passing over this space without any draught is a great deduction from his absolute force: so also in a man, if his effort is such as to require locomotion, all the muscular power employed in the mere translation of his body over this space is lost as to mechanical effect, and accordingly it is found that a man will produce the greatest mechanical result when he is fixed in his place, as at a winch or rowing in a boat; for although in the latter case he is really transferred from place to place, it is at little expense of muscular force. At a winch, the only non-efficient muscular exertion is that of raising the centre of gravity of the body from the lowest stooping position to the upright position. In rowing, it is bringing the body from an inclined position backwards to the same forward, and this being less than the former, the man is found capable of producing more useful effect in this mode of applying his force than in any other. The next best mode of application is at the winch, and the third at the capstan bar, for here, although there must be considerable locomotion, yet the direction of his muscular power is advantageously applied; and where the purchase is great and the duration of the effort small, there is perhaps no other way of employing a man's muscular power to so great advantage.

A method of employing the power of men for involuntary labour has been recently introduced into this Country, called the Tread-wheel, which will be described in a subsequent page amongst the simple Machines; and we shall in this place only observe upon it, that the effort required here, is for the man to be constantly lifting his

Machinery.

Maximum
effect

Men on a
Tread-
wheel.

Manufactures.

own weight; as a medium we may therefore consider him lifting a weight of 140 or 150 pounds, whereas we have seen that the most useful effect is produced when the man is opposed to only about 30 pounds. Consequently, although in this machine there is no lost effort in locomotion, yet the load exceeding that which gives the maximum effect nearly five times, it is a very disadvantageous mode of application, however proper it may be for employing the idle and disorderly. It will be seen under the article Tread-mill that the maximum effort of a man in this mode of application cannot be stated at more than 3750.

Men unloading coals.

(6.) Another way in which the power of men is employed to a considerable amount, is, in unloading the colliers on the river Thames, and a more disadvantageous mode of application can hardly be conceived; none but the strongest and most robust men can undertake it, and while at work the exertion is so great, that they work almost naked, and yet after all the amount of labour in actual numbers is scarcely half the above effect at the Tread-mill.

The way in which this operation is conducted is as follows: a stageing is erected about seven feet above the deck, upon which the coals are first lifted, and thence shot into barges. The number of men employed are

Four men in the hold filling,

Four men for what is called whipping,

One man at the basket.

The quantity of coals brought up each time is $1\frac{1}{4}$ hundred-weight, and the mean depth of the centre of gravity of the coals is about 20 feet below the platform; a pulley is placed in the rigging, over which a rope passes to the hold, and to which the basket, when filled, is attached. The four whippers now run up a sort of step-ladder, 5, 6, or 7 feet, according to circumstances, each having in hand a rope, which unites in the one which is attached to the loaded basket, then each using his greatest effort catches up a certain length of rope, thereby raising the basket a little, and then all jumping down at the same time and using still a considerable further muscular effort when down, the coals are raised to the platform with a sudden jerk.

The quantity these nine men will raise per day, in a general way, varies from 60 to 80 tons; but we are informed they have raised as much as 200 tons; and a gentleman on whom we can rely says he has had 105 chaldrons, or about 126 tons, whipped out in one day, but it was considered a great day's work. Of these nine persons four only are employed in lifting, and reckoning only these four we shall see how very inadequate the result is compared with the labour.

Let the day's work be 20 tons for each of these men, raised 20 feet, this gives $20 \times 20 \times 2240 = 896,000$ pounds raised a foot high in the day, or $\frac{896,000}{8 \times 60} = 1866$

pounds one foot high in a minute, which is not one-third of what has hitherto been considered a man's power, nor half the reduced measure of it we have assumed in the preceding page from the most recent experiments, and only just half the Tread-mill day's work, although this, as we have seen, is itself a disadvantageous mode of application. We are aware that the nature of the work to be performed must, in many cases, determine the mode of application of the power, whether advantageous or not; but we are strongly of opinion there is no occasion in this case, in unloading a vessel of coals, to be confined to this absurd way of what is called whipping.

These are the principal cases in which the muscular

power of man is employed as a first mover, except where the force required is so small as not to require further aid, or where skill as well as power is necessary to the operation. It seems indeed a reasonable inference from all that has now been stated, that man was designed by his Maker for a higher principle of action—for the exercise of skill and for invention; to regulate the action of the lower animals to the purposes of labour, to convert air, fire, and water to his service, and, only where skill and direction are required, to become himself a mechanical agent.

Machinery.

(7.) *Of the Wind as a first mover.*—Of all mechanical agents the Wind is the most uncontrollable, the most uncertain, and its effects the most difficult to estimate, not from any mystery in the nature of its action, but simply from its natural variability. If we could regulate the velocity of the Wind impinging upon a body to be moved by it, there would be no difficulty in reducing its action to a comparison with other forces, but its perpetual changes, not merely in direction but in power, render such a reduction nearly impossible. If the velocity could be determined and remained constant, the pressure of the Wind on any given surface might be easily computed, it being equal to the weight of a column of air of the density of the atmosphere, of such a height that a heavy body falling from that height would acquire the given velocity. Now taking the mean density of the air to that of water as $\frac{1}{800} : 1$, we may easily compute the

Power of the Wind as a first mover.

pressures in pounds avoirdupois, upon a square foot of surface, and hence of course the pressure for any surface. Let v be the velocity in feet per second, then g denoting $16\frac{1}{2}$ feet, the space fallen by a heavy body in a second, we have $v = 2 \sqrt{gs}$ or $s = \frac{v^2}{4g}$ for the height of the column of air, the pressure or weight of which on a square foot will therefore be (taking the cubic foot of water at $62\frac{1}{2}$ pounds) $p = \frac{62\frac{1}{2} v^2}{3200 g}$ pounds. This theo-

retical deduction, however, it appears, does not agree with actual observation, when the velocities are considerable, the cause of which is probably to be found in the elastic nature of the air; and as our inquiries here are rather practical than theoretical, we shall content ourselves with merely stating the actual observed pressures on one square foot of surface at different velocities, as given by Mr. Smeaton, in the *Philosophical Transactions*, vol. li.; see also Hutton's *Abridgement of Phil. Trans.* vol. xi.

Miles per hour.	Feet per Second.	Pressure per square foot, in pounds.

Manufac-
tures.
Maximum
effect.

Having thus the perpendicular force of the Wind on a given surface, we have to consider the manner in which it can be applied for mechanical effect; and this is commonly by means of windmill sails, which are placed obliquely to the plane of their motion and to the direction of the Wind, so that, the latter impinging upon them, its force is resolvable into two forces, one according with the direction of the motion of the sails, and the other perpendicular to it: by the former of which rotation and mechanical effect are produced. Here then again arises another question, what ought to be the angle of the sails' obliquity, to produce the best effect? If we had merely to determine the angle at which the sails should be placed to receive the greatest impulse from the Wind at right angles to its direction, the sails being supposed at rest, we should find it to be 45° , but this angle would not give the greatest velocity: to attain this the angle requires to be about 55° ; but neither of these angles will give the greatest mechanical effect. In the windmill, as in all other Machines, a certain velocity opposed to a certain weight is requisite for the maximum effect; and generally speaking, these are far better obtained from actual experiment than from theoretical deductions, however valuable the latter may be in guiding our first experimental researches. On this head we shall offer some remarks in our description of this important engine, our only business in this place has been to give a general illustration of the nature of the Wind as a first mover. The angles of inclination of the sails, their size, form, and general arrangement, will be best treated of in the article referred to.

Water as
a first
mover.

(8.) *Of Water as a first mover.*—Water acts as a first mover either by its weight only, by its momentum only, by its weight and momentum combined, or by its pressure. In the former cases it commonly is made to act on a wheel, and in the latter by its action on a piston.

Balance
wheel.

The nature of its action on different wheels, in these several cases, will be more particularly described under the article Water mill; it will be sufficient here merely to explain the general character of its action. In the former case the circumference of the wheel is supplied with a number of buckets, the shape and number of which will be explained in the article referred to; the Water is received into these buckets above the centre or axle of the wheel, and thus, being heavier on that side, motion will ensue, and as fresh buckets arrive at the proper height to receive the Water, while those below have emptied themselves, a constant tendency to motion is created and rotation is produced. A wheel of this kind is called a *balance wheel*.

Overshot
wheel.

When the Water instead of being received into the bucket on its own level, is allowed to fall from a certain height, being commonly in that case conducted over the top of the wheel, it acts first by its momentum and then by its weight, although the former part of the effect is but small. This wheel, which differs however in no respect in its form from the former, is called, in consequence of the manner in which it receives the water, an *overshot wheel*.

Undershot
wheel.

When the Water acts by its momentum only, the circumference of the wheel, instead of being supplied with buckets, as in the preceding case, is now furnished with floats or float boards, and being exposed to the action of a running stream, generally increased in rapidity by a previously regulated fall, is thus driven round, and its force communicated to any Machinery intended to be worked by it. This is called an *undershot wheel*.

Sometimes instead of the Water having a previous fall and thereby being made to strike the floats at the bottom of the wheel with an increased velocity, the wheel is fixed in what is called a *race*, formed of stone work, agreeing with the curvature of the wheel, and being thus let on from its own level, acts both by its weight and momentum. This is called a *breast wheel*. This wheel differs in its form from the last in this, that it must necessarily be close boarded, or technically close *soled* round its circumference, whereas the other is an open wheel; the sides are also sometimes close *shrouded*, or closed in on the sides to retain the Water, and it thus becomes a sort of bucket wheel, although in consequence of the Water being retained by the sides of the race these buckets are not made of the same shape as the former. In some cases the shrouding is omitted, in which case great accuracy is requisite in forming the race and hanging the wheel.

Machinery
Breast
wheel.

The above are the principal methods in which Water is made to act as a first mover, and our object here is simply to ascertain, as far as we are able, the amount of its action in any given case, in terms of our dynamic unit or horse-power, but unfortunately this is not very easily, or at least not very satisfactorily to be accomplished.

(9.) If the head of Water thrown upon an overshot or balance wheel produced its whole effect, we should be able at once to state the amount of that effect in horse-powers, but unfortunately there is still great uncertainty in the relation between the actual head and discharge of Water, and the mechanical effect it produces in different cases; and the same remark applies also to the undershot wheel, and more strongly still to the breast wheel. From several experiments by Mr. Smeaton, it appears, that in overshot Water wheels the ratio between the power and effect, at its maximum, varies from that of 10 to 7.6, to that of 10 to 5.2, or nearly from 4 to 3, to 4 to 2; the former belonging to those cases where the quantity of Water expended was the least, and the latter to those in which the quantities were greatest; and he therefore assumes 3 to 2 as a medium ratio between the power and effect in overshot wheels, while in undershot wheels the ratio between the power and effect, at a maximum, is as 3 to 1. The ratio therefore of effect in overshot wheels and undershot wheels, both acting to the best advantage and under the same circumstances of quantity and fall, at a medium, is as 2 to 1.

Compara-
tive power
of Water
wheels.

Now these ratios, if they rested upon a tolerable certain basis, would enable us at once to compare the effect of a Water wheel with the unit of mechanical force, and consequently with the power of a horse or steam-engine. We should only have to estimate the quantity and weight of Water fallen in a minute, and the amount of the mean fall in feet; then multiplying the weight in pounds by the number of feet, and dividing the product by 33,000, would give the amount of the motive force in horse-powers, and two-thirds of this, according to the proportions above stated, would be the useful effect in the overshot wheel, and one-third of it in that of the undershot wheel.

Unfortunately, however, the above ratios, which are drawn from experiments on a comparatively small scale, and where every precaution was taken to ensure accuracy, and which still gave only an assumed mean between one half and three-fourths, cannot be applied with any certainty in real practical cases; so that after all, notwithstanding they may assist us in some degree in estimating the effect which may be expected to be obtained from a given head and fall, the subject must always be ap-

**Manufac-
tures.** proached with caution and deliberation, particularly where the work to be performed cannot be effected without a certain amount of power, as in the case of Rolling mills and others of a similar kind.

We have mentioned the case of Water under compression being employed as a motive power; this occurs, however, only in a few instances, and then principally from considerations of convenience, as in the case of Bramah's Planing machine, and a few others; it is therefore not that description of motive power which requires to be considered in this place.

**Steam as a
first mover.** (10.) *Of Steam as a first mover.*—This is a subject on which it will be necessary to enter at considerable length, when we have to treat of the Steam-engine; we shall therefore be in this place as concise as possible, in speaking of its mechanical effects as a first mover, the principles on which the estimation of the power depends, and the usual allowances made for friction, imperfect vacuum, and reduction of temperature; all which subjects must be examined at considerable length in the article referred to. For the present purpose it will be sufficient to state generally, that in a Steam-engine, the power obtained depends upon the difference of pressure of the Steam against the piston on one side, and that of the vapour or imperfect vacuum on the other, and on the area and velocity of the piston, without regard to its length. To estimate the actual power from these data only, however, would not give a measure of the useful effect of an engine, because a part of this power is employed in producing the vacuum, and in overcoming the friction and inertia of the different parts; certain allowances therefore become necessary, which we shall content ourselves with merely stating in this place, reserving the examination of the principles on which they rest, till we have to treat of the engine itself.

Every body knows that the medium pressure of the atmosphere, and of Steam at the boiling heat of water, is about equal to 30 inches of quicksilver, or to 34 feet of water, or to $14\frac{3}{4}$ or 15 pounds on each square inch of surface pressed. If therefore we had a pressure of Steam on one side the piston only, equal to the pressure of the atmosphere, and a perfect vacuum on the other, the power would be equal to 15 times the number of inches in the area of the piston, in pounds avoirdupois; but in the common low-pressure engine the Steam in the boiler is generally kept at a pressure of from $2\frac{1}{2}$ to 4 pounds, exceeding the atmosphere, and instead of a perfect vacuum, on the other side, or in the condenser, the pressure of the vapour, &c. amounts to about 2 pounds; that is in common language it is said to have a minus pressure of about 13 pounds, or equal to a column of mercury of about 26 inches, varying from this to 28 inches, according to the perfection of the workmanship and other causes. Suppose, as an example, that the minus pressure is equal to 26 inches, or 13 pounds, and the pressure of Steam on the piston to be the same as in the boiler, 4 pounds, that is allowing for no loss of temperature in the passage of the Steam, then the actual motive power of the piston would be $4 + 13 = 17$ pounds upon every square inch of its surface. This, however, is not all effective power; a considerable portion of this is absorbed

in working the air-pump to produce this imperfect vacuum Machinery. and in overcoming the friction and inertia of the Machine, the latter being always considerable, in all reciprocating parts, as the pistons, the beam, &c. We cannot of course in this stage of the inquiry enter into an examination of the effect of all these counteracting causes; we shall therefore content ourselves by merely stating at present that about one half of the minus power is consumed in the way we have stated, in the reduction of temperature and the consequent reduction of the elastic power of the Steam in its passage from the boiler to the cylinder, and to the still further reduction in the latter part of the stroke in consequence of the Steam being shut off before the stroke is completed. All these circumstances considered, it is found in practice that the actual effective power of the engine is equal to a pressure estimated by half the minus pressure of the condenser, plus the pressure shown at the boiler, beyond that of the atmosphere; so that in the above case, the actual effective power would be $6\frac{1}{2} + 4 = 10\frac{1}{2}$ pounds, and this multiplied by the area of the piston in inches, and its velocity in feet per minute, and the product divided by 33,000, the quotient will show the number of nominal horse-powers of the engine, each horse-power being, as has been already stated, equivalent to $1\frac{1}{2}$ times the actual medium power of a horse. A more detailed examination of the power of Steam will be found in the Chapter on the STEAM-ENGINE.

What is above advanced is perhaps sufficient for our present object, which has been merely to give a general idea of the comparative power of the principal first movers, by means of one common standard or dynamic unit. It is obvious from all that has been stated that much uncertainty must after all hang upon the comparison. The powers of men and animals differ very greatly, each in its class. The power or rather the velocity of the Wind is exceeding uncertain and variable. Water is also liable to considerable fluctuations in supply, and great impediments interfere in the action of large heavy wheels; and even in the steam-engine its action is not uninfluenced by atmospheric changes, and of course much also of its power depends upon the accuracy of workmanship, the care and diligence of the engineer, and various other circumstances; so that the comparative value we have been enabled to assign to the several first movers under consideration, must be taken as they are given, not as absolute and certain, but as the best medium results that can be obtained, where all the elements on which they are founded are so variable and capricious.

(11.) It may not be uninteresting to the reader, in concluding these few remarks on the relative power of men, horses, windmills, water mills, and steam-engines, to give the following Tabulated results, collected with great care by Dr. Young, and published in his Lectures on Natural Philosophy; remarking only that on a full comparison they will be found to differ considerably from each other, and we trust will justify what has been repeatedly stated in the preceding pages, relatively to the uncertain data on which all comparisons of this kind must rest.

A man going up stairs ascends 14 metres in 1". Coulomb.....	1.6	0 1 0	
A man going up stairs for a day raises 250 chilogrammes to the height of a kilometre. Coulomb....			.653
With a spade a man does ½ as much as in ascending stairs. Coulomb.....			.533
With a winch a man does ⅓ as much as in ascending stairs. Coulomb.....			.345
A man carrying wood up stairs raises, together with his own weight, 100 chilogrammes to 1 kilometre. Coulomb.....			.299
A man weighing 150 pounds Fr. can ascend up stairs 3 feet Fr. in a second, for 15" or 20". Coulomb.	7.01	0 0 20	
For half an hour 100 pounds Fr. may be raised 1 foot Fr. in a second. Coulomb.....	1.52	0 30 0	
According to Mr. Buchanan's comparison, the force exerted in turning a winch being made equal to the unit, the force in pumping will be.....	.61		
In ringing.....	1.36		
In rowing.....	1.43		

According to Schulze's experiments, the force which a man or a horse can exert with the velocity v , is $= f \left(1 - \frac{v}{a}\right)^2$ f being the force in equilibrium, and a the velocity without resistance. This is a formula of Euler.

Another of his expressions, $f \left(1 - \frac{v}{a}\right)$, does not agree so well with Schulze's experiments, but Euler's theory is founded on assumptions wholly arbitrary. According to the first formula, the greatest mechanical effect would be when $v = \frac{1}{2} a$; according to the second, when $v = \sqrt{\frac{1}{3} a}$.

Allowing the accuracy of Euler's formula, confirmed by Schulze, supposing a man's action to be a maximum, when he walks $2\frac{1}{2}$ miles an hour, we have $7\frac{1}{2}$ for his greatest velocity, $.04 (7\frac{1}{2} - v)^2$ for the force exerted with any other velocity, and $.016 v (7\frac{1}{2} - v)^2$ for the action in

each case; thus,

When the velocity is one mile an hour, the action is ..	.929
When two miles.....	1.31
Three.....	1.33
Four.....	1.07
And when five.....	.682

And the force in a state of rest, $2\frac{1}{2}$ or about 70 pounds, with a velocity of two miles 36 pounds, with three 24 pounds, with four 15. It is obvious that in the extreme cases this formula is inaccurate, but for moderate velocities it is probably a tolerable approximation. Porters carry from 200 to 300 pounds at the rate of three miles an hour; chairmen walk four miles an hour with a load of 150 pounds each; and it is said that in Turkey there are porters who, by stooping forward, carry from 700 to 900 pounds, placed very low on their backs. The most advantageous weight for a man of common strength to carry horizontally is 111 pounds, or if he returns unladen, 135. With wheel-barrows men will do half as much work as with hods. Coulomb.

By means of pumps a horse can raise 250 hogsheads of water 10 feet high in an hour. Smeaton's Reports.....		4.96	1 0 0	

Manufactures.

A horse can in general draw no more up a steep hill than three men can carry, that is from 450 to 750 pounds, but a strong horse can draw 2000 pounds, in a cart, up a steep hill which is but short. Desaguliers.

The diameter of a walk for a horse mill ought to be at least 25 to 30 feet. Desaguliers.

Some horses have carried 650 or 700 pounds seven or eight miles without resting, as their ordinary work; and a horse at Stourbridge carried 11 hundred weight of iron, or 1232 pounds, for eight miles. Desaguliers.

A windmill with four sails, measuring 66 feet Fr. from one extremity to that of the opposite side, and 6 feet wide, or a little more, was capable of raising 1000 pounds Fr. 218 feet in a minute, and of working, on an average, eight hours in a day. This is equivalent to the work of 51 men, as it has been above estimated; 25 square feet of canvass performing about the daily work of a man.

Smeaton says that he has experimentally found a 30 feet sail equal to four horses, or one sail equal to one horse or five men, which, taking the breadth at 4 feet, nearly agrees with the above.

On the Advantages and Disadvantages of different First Movers.

Economy in the selection of first movers.

(12.) In the Introductory Chapter to this Treatise, economy in the subdivision of labour has been considered, and the advantages attending its adoption have been explained at considerable length; but those remarks have in general reference to the employment of labourers, whether men, women, or children, and the basis of it depends upon the dexterity which a person will acquire, and the conveniences which may be rendered him, while he is kept engaged in one particular mechanical process which requires skill rather than strength. Our present object is to inquire into the expense and economy resulting from the nature of the first movers, in which power and not skill is the object to be attained. If we look merely to the pecuniary charge of different first movers, this question would require but little investigation; but there are other considerations, and some of them perhaps scarcely appertaining to our present inquiry, which render the subject in some cases very difficult and perplexing.

We have seen that a horse will perform as much labour, where no skill is required, as five men, and that what is called a horse's power in a steam-engine, is, at the lowest estimate, equal to $1\frac{1}{2}$ times the actual power of a horse, and consequently to $7\frac{1}{2}$ men. We may also state, that, at a medium, 10 pounds of coals in a steam-engine will supply the requisite fuel to produce a horse-power per hour, or about 80 pounds per horse-power for a day, working only 8 hours.

Now the value of 80 pounds, or about a bushel of coals, we can scarcely estimate at more than 1s., the expense of $1\frac{1}{2}$ horse-keep will be perhaps, at a medium, about 3s. 6d., while the expense of $7\frac{1}{2}$ men, at the medium rate of wages for good English labourers, will be 21s. Here then, looking only to the motive power, the relative expense in these three cases, will be about as the numbers 3, 7, and 30. This, however, is not a fair view of the subject, because in the latter case the whole expense is included, whereas in the horse we must consider the first purchase, the expense of harness, stabling, shoeing, grooming, &c.; this perhaps may raise the daily expense of the horse to 4s. 6d.; and in the steam-power we have also, besides the expense of fuel, to include that of oil, tallow, the engineer, stoker, the

first purchase, erection of building; and this will probably, in a medium-sized engine, amount to another shilling per day, and our relative expenses will then be steam power 3s. per day, horse power 6s. 9d., labour power 15s. per day.

Machinery.

The expense of the other sources of mechanical agency cannot be so well estimated; the motive power in a windmill of course costs nothing, and in a water mill it is uncertain, being a hire at a greater or less charge, according to circumstances; both these Machines, however, are worked at considerably less expense than the steam-engine; but the one is uncertain and scarcely available to any process where steady and constant results are required, and the other, although subject to less uncertainty, is only a local power, and cannot be, like the steam-engine, made available in all situations. The question of economy and expense, therefore, rests between the man, the horse, and the steam-engine; and here, it must first be taken for granted, when we make a comparison of this kind, that there is sufficient employment for the steam-engine; for if this is not the case, the expense, as compared with the value of its production, is much increased; its power will be also deteriorated, for want of being kept regularly at work; and its wear and tear, while it is at work, will be considerably increased, and its final duration much shortened. We have lately seen one of the earliest of Bolton and Watt's engines, which has been in constant use above forty years, performing admirably; it has of course undergone certain repairs, and certain parts have been replaced by new work; but had this engine worked only a day or two in a week, or for a week or two in a month, it is not unlikely that it would long before this have been entirely worn out and rejected. There are, it is true, some cases where great power is required, although not wanted to be in constant application, that is where only an engine of a large kind is competent to produce the desired effect. In such cases, notwithstanding the above consideration, a powerful engine must be procured; but these instances lead merely to considerations of expediency and necessity, and form no part of the question of economy, as regards the application of other first movers.

The point to which we are desirous of directing attention, is where the demand is such as to give due employment, and where the inquiry is merely whether it will be best to employ horse or steam-power, or horse or man-labour; for there is seldom a question between the employment of the power of man or steam, although there are some such, as in cotton-spinning-engines, power-loom weaving, &c.

Where the question is between horse and steam-power, we have already seen the great advantage, in point of expense; but this is not all the advantage, nor all that enters into the question of what is to be understood by the term economy. We have to look to the convenience of application, the steadiness and uniformity of power and motion, and if it did not rather belong to a different inquiry, we might point out its bearing upon the national advantages and resources. There is no doubt horses, like all other objects of sale, are supplied in the market, we may say produced, in proportion to the demand; every new application of steam therefore to effect what had hitherto been effected by horses, either serves to diminish the value of horse-labour, or the number of horses in the Country.

On the former supposition, other articles produced by horse-labour are reduced in price, and conveniences

Manufac-
tures.

depending on horses are obtained at a cheaper rate ; or on the other hand, so many less horses are to be maintained, and the land which supplied their food is now available to the support of man ; besides which, the demand for human labour is increased. Miners must be employed to extract the coal ; ships built and sailors to transport them ; artificers to erect the necessary buildings, and engineers are wanted in greater numbers to form steam-engines than horse-mills ; and after all, the article produced may be purchased by the general consumer at much less price. We must conclude, therefore, that where the demand is sufficient, steam-power is in every respect preferable to horse-labour.

The question is not quite so simple in comparing horse with man-labour. As far as regards the expense, indeed, we have already seen that it is at least two to one in favour of horse-power ; but what were in the former comparison advantages, in a national point of view, are the contrary in this. If the substitution of steam-power for horse-power have a tendency to diminish the number of horses, and thereby to reduce the price of human food, it follows that the substitution of horse-labour for man-labour tends to increase the number of horses, and to increase the price of human food. However little doubt there may be therefore in considering merely the first expense to individuals, the substitution is very questionable when looked at under a more comprehensive point of view ; and this is more particularly the case, if, while the horses are made to work, men are obliged in consequence to remain idle, which it is to be feared is too often the case, in our agricultural districts, where the thrashing machine supplies the place of the flail, which is an operation requiring some skill as well as strength, and therefore not degrading to a man, as it would be to make him the immediate motive agent in the thrashing machine itself.

The same objection does not apply to the substitution of steam-power for man-labour in our manufacturing districts, but quite the contrary ; for in the first place this abstracts no land from the production of human food ; and although every such new substitution must throw some hands out of employ, the general demand is so much increased by the cheapness of the production, that these again are soon called into action ; every body is more cheaply clothed ; and the general exportation of the article being increased, calls for additional labour, and thus contributes to the riches and resources of the Country.

As a proof of the extraordinary advantages of this substitution, we may mention the following fact : that in 1767 the number of hands engaged in our Cotton manufactories did not amount to 30,000, the article was dear, and few the number that could indulge in its use, either for dress or household purposes ; at this time, in consequence of the skill which has been bestowed in the substitution of Machinery for manual operations, instead of employing 30,000, we have employment for upwards of a million, and the article being furnished to the consumer at less than a quarter of its former price, it is now in general use with all, even the lowest classes of society. But we shall never be able to trace such results to the substitution of horse for man-labour.

To pursue the question beyond this point, would be to enter into a discussion on Political Economy, which is not within our province. Our only object has been to compare mechanical expenses and economy, and if we have deviated a little from this line of argument, it has not been

a matter of choice but of necessity, in consequence of Machinery the intimate connection of the two subjects.

II. OF RETARDING FORCES.

(13.) If Machines could be made perfect, the effect produced by any combination of mechanical powers would lead to results precisely equivalent in measure to the forces by which motion is produced ; but in no Machine can this be expected, in consequence of the retardation to which all are necessarily liable ; such as friction, rigidity of cords, ropes or bands, the resistance of the air, &c. Of these counteracting forces, however, it will perhaps be sufficient merely to examine the amount of the two former ; for although the resistance of the air is sometimes considerable, and is even in a few cases designedly introduced to regulate the motion of a Machine, yet generally it is not considerable, and its retardation may therefore be neglected, except in those cases to which we have alluded, and which will be treated of more appropriately in another article than in this place.

On friction.—In the article STATICS, in our Treatise on Amount of Theoretical Mechanics, we have investigated the theory of friction. friction, as far as its influence affected the sensibility of the equilibrium of bodies ; but we have reserved its dynamic effect, or its influence on the motion and force of moving bodies, for the present article ; although by mistake in the article in question its place is referred to the general alphabetic arrangement. In all investigations relative to the dynamic effect of moving bodies, we are under the necessity, in theory, of considering the surfaces of bodies as perfectly smooth, and that they slide over each other without resistance. But this is far from being the practical state of things : there are no bodies perfectly smooth, nor any Machine that is not more or less impeded in its motion by friction, or the rubbing of its parts, whether it be the teeth of wheels against each other, pivots and gudgeons against their bearings, or in fact any one surface pressing and rubbing on another ; indeed in many Machines, such as Polishing mills, Grinding mills, Boring and Sawing mills, &c. the entire effort is to overcome friction or something very much resembling it ; so that a knowledge of its nature and effects seems absolutely necessary to enable us to apply the principles of theoretical mechanics to useful practical purposes.

Much attention has been accordingly paid to this subject, by many distinguished philosophers and practical engineers, but by far the most extensive series of experiments and the most valuable deductions are those which we owe to George Rennie, Esq. F.R.S. published in the *Philosophical Transactions* for 1829, from which we shall take the liberty of extracting and abbreviating those parts which belong more immediately to our present inquiry. The author introduces his experiments by a short sketch of previous attempts. The nature of friction, he observes, has excited the attention of most of the writers on practical Machinery from the period of the first two Dissertations of Amontons, in the year 1699, down to the more elaborate researches of Coulomb and Vince, in 1799 and 1784. Amontons affirmed that friction was not augmented by an increase of surface, but only by an increase of pressure ; and from subsequent experiments drew a conclusion that friction amounted to one-third of the pressure, and the amount was the same both with wood and metals when unguents were interposed. He likewise concluded that friction increased or diminished with the velocity and varied in the ratio of the weight and pressure of the rubbing parts, and the time and

Manufactures. Different writers on friction. velocity of their motions. These hypotheses were adopted, more or less, by most of the Philosophers after Amontons, but particularly by De la Hire, who satisfied himself by several experiments of the truth of Amontons' conclusions, but they were questioned by Lambert, although without the test of experiments. Parent suggested an investigation of these subjects in his proposition of the spheres, by determining the angle of equilibrium at which a body, resting on an inclined plane, commenced sliding; and the celebrated Euler, in a very elaborate paper, conceived it to depend upon the greater or less approximation of the asperities of the surface, brought into contact by pressure, the resistance to which, in agreement with Amontons, he allows to be one-third of the pressure. Of the effect of velocities he was however uncertain; but observed that when a body begins to descend an inclined plane, the friction of the body will be to its weight or pressure as the sine of the plane's elevation to its cosine, &c. But when the body is in motion, the friction is diminished one half. Muschenbroek and others maintained that friction increased with the surface; and Bossut distinguished it into two kinds; the first being generated by the gliding, and the second by the rolling of the surface of a body over another; and remarked, that it was affected by time, but that it followed neither the ratio of the pressure nor of the mass. Brisson attempted to construct a Table of coefficients, to denote the value of the friction of different substances; but they are inapplicable to practical purposes, for want of proper experiments. Desaguliers considered the nature of friction with a good deal of attention, but principally with reference to the rigidity of cords. He, however, quotes the experiments of Camus, as best calculated to illustrate the subject; nevertheless, they were made on too small a scale to derive any satisfactory conclusions. Schober and Meister coincided with Muschenbroek in the opinion, that the spaces were as the squares of the times, in the case of a body uniformly accelerated. The opinions of many other eminent Philosophers, such as Leibnitz, Varignon, Leupold, Bulfinger, Daniel Bernoulli, Ferguson, Rondelet, Gregory, Leslie, Young, Olivier, &c. might be quoted. But it is to Coulomb, principally, that we are indebted for the knowledge we possess of this kind of resistance.

Coulomb. (14.) In the year 1779 the Academy of Sciences, at Paris, being desirous of rendering the laws of friction, and the effects resulting from the rigidity of cords, applicable to Machines, Coulomb undertook, in the Arsenal at Rochfort, a very extensive series of experiments, which he afterwards published in 1781, under the title of *Théorie des Machines simples, en ayant égard au Frottement de leurs Parties, et à la Roideur des Cordages*. This Memoir is divided into two parts. The first treats of the friction of surfaces gliding over each other, and the second enters into an examination of the rigidity of cords, and the friction of the rotary movements of axles. Coulomb commences his Work by examining the friction of plane surfaces gliding over each other, distinguishing it into two kinds; the first resulting from time, and the second from velocity. The first may depend on four different causes; viz.

- 1st. The nature of the bodies in contact.
- 2d. The extent of surface.
- 3d. The pressure on the surface.
- 4th. The time the surfaces have been in contact; and he even adds a

VOL. VII.

5th. The state of the atmosphere; which he however Machinery. thinks may have little influence.

The case of bodies gliding over each other with a certain velocity, he considered to be referable to the first three causes, besides the velocity of the planes in contact.

With regard to the physical causes of friction, he coincides with the opinions of Amontons and others, that it arises from the entangling of the asperities, which can only be disengaged by bending or breaking. These experiments led to some important results; viz.

1st. That the friction of wood on wood without unguents, was in proportion to the pressure, which attained its maximum in a few minutes after repose.

2d. That the effects of velocities were similar; but the intensities were much less to keep the body in motion, than to detach it from a state of rest, oftentimes in the ratio of 22:95.

3d. That in the case of metals, the results were likewise similar, but the intensity was the same, whether to disturb or maintain the motion of the body.

4th. That with heterogeneous surfaces, such as those of wood and metals gliding over each other, the intensity did not attain its limit sometimes for days.

In general, however, with woods and metals without unguents, velocities were found to have very little influence in augmenting friction, except under peculiar circumstances.

The Treatise of Coulomb is illustrated by a great variety of interesting experiments, and forms the most valuable Work we possess on the subject.

(15.) In the year 1784, Dr. Vince endeavoured by Vince some very ingenious experiments to determine the laws of retardation, together with the quantity and the effect of surface on friction. The results were, that the friction of hard bodies, in motion, was a uniformly retarding force, but not so with cloth and woollen, which were found, in all cases, to produce an increase of retardation, with an increased of velocity.

That the quantity of friction amounted to about one-fourth of the pressure, and that it increased in a less ratio than the quantity of matter or weight of the body.

That when the surfaces varied from 1.61:1 to 10.06:1, the smallest surface gave the least friction: and finally, that friction was greatly influenced by cohesion.

Dr. Vince's conclusions regarding the laws of retardation, were partly confirmed by the late ingenious Mr. Southern of Soho, who in a Letter to Dr. Vince, in 1801, communicated the results of several experiments on the surfaces of the spindles of grindstones, moving with great velocities; when it was found, that with the rubbing surfaces, moving at the rate of 4 feet per second over a length of surface of 1000 feet, the resistance, arising from the friction of 3700 pounds of matter, only amounted to one-fortieth of the weight.

(16.) Mr. Rennie having given the above interesting Rennie's detail of previous experiments, proceeds to describe those experiments. made by himself; the scale of which far exceeded any previously undertaken, the pressures employed in many cases amounting to several hundred weight. The apparatus consisted of a plane horizontal bed, but which might be elevated to any proposed angle; and the measure of the friction was accordingly obtained in two ways; first by determining the weight on a scale requisite to draw a given load along the horizontal plane, and secondly, by elevating the plane till the angle was such as to cause the effect of Gravity to just overcome the friction. In the latter case, we know that when a

Manufactures.

body is just sustained on an inclined plane, the weight of the body, the pressure on the plane and its force parallel to the plane vary as the radius, the cosine, and sine of the plane's elevation, and therefore the weight being w , the amount of the friction will be

$$\sin a \cdot w = \frac{w}{\operatorname{cosec} a}. \quad \text{Whence, the angle being given,}$$

the cosecant of that angle will express the fraction of the weight which is equivalent to the friction.

Friction of wood on wood.

This being premised, and passing over the first experiments of cloth on cloth which are not immediately applicable to our present inquiry, we come to those of wood on wood, from which the following abstract has been made, and will be found very valuable. The plane was here placed horizontally, and the rubbing surface measured two square inches. The mean stated in the Table is obtained by taking the general mean of all the results drawn from experiments on weights, varying from half a hundred weight to ten hundred weight, thirteen hundred weight, &c. And in order to show the greatest variability in the law obtained, we have stated the two extreme results in two separate columns with the weights with which they occurred.

TABLE I.—Of the Friction of Wood on Wood.

In these experiments a descending weight was made to draw another along a horizontal bed or plane.

Nature of the rubbing surface.	Mean of weight to friction.	Number of experiments from which the mean is taken.	Weights moved.	Weights which gave the least ratio.	Weights which gave the greatest ratio.
Red teak on red teak	8.82 to 1	13	from 1 cwt. to 13 cwt.	cwt. 1	prop. 9.90
American live oak on American live oak	7.65 to 1	12	from 1 cwt. to 12 cwt.	cwt. 8	prop. 9.15

Elm on elm	5.86 to 1	9	from 1 cwt. to 8 cwt.	cwt. 1	prop. 6.38
Honduras mahogany on Honduras mahogany	5.96 to 1	12	from 1 cwt. to 11 cwt.	cwt. 1	prop. 6.76
Yellow deal on yellow deal	2.88 to 1	6	from 1 cwt. to 5 cwt.	cwt. 5	prop. 3.03
White deal on white deal	3.81 to 1	3	from 1 cwt. to 2 cwt.	cwt. 2	prop. 4.94

The results as above given having been obtained by Machinery. a descending weight drawing another along a horizontal plane they were afterwards repeated, or extended, by determining the least angle at which the weight on the inclined plane began to slide. These are given in the following Table, the proportions being obtained from the formula already given; viz. $f = \frac{w}{\operatorname{cosec}}$.

TABLE II.—Of Friction of Wood on Wood.

In determining which, the bed on which the weights rested was inclined till the body slid.

In reference to the two preceding Tables of experiments Mr. Rennie remarks, "that there is a great deal of irregularity in the results; increase of pressure scarcely increasing the resistance. This may arise in some measure from the surfaces becoming condensed, and thus rendered less liable to abrasion. In some of the cases abrasion had already commenced, but it was not convenient to pursue the experiment further. The soft woods present more resistance than the hard woods, yellow deal on yellow deal being the greatest, and red teak on red teak the least.

(17.) According to Mr. Knowles of the Navy Office, the weight of the Prince Regent of 120 guns on the slips previous to launching was 2400 tons, which divided by the area of the sliding surface of her bilge-ways, (equal to 149,184 square inches,) gives a pressure of 36 pounds per square inch. But the weight

of the Salisbury, of 58 guns, on the slips, according to the area of her bilge-ways, was 44 pounds per square inch. Now by the foregoing Table, the average force required to put in motion the three different kinds of oak under a pressure of 56 pounds per inch is about one-eighth of the pressure, which proportion prevails as high as six hundred weight per inch area; and by Table VI. we find that soft soap, (the ingredient mostly used for diminishing the friction of bilge-ways,) under a pressure of 56 pounds per inch, gives about one-twenty-sixth of the pressure for the friction. Hence the angle at which a building slip should be laid can be easily determined. Coulomb even makes 49 pounds per square inch, and one twenty-seventh for the pressure for hog's lard

The weight of the middle arch (of 151 feet 9 inches span) of the New London Bridge, together with the

centres, was 4900 tons. This acting upon the surface of the striking wedges equal to 540 square feet gives a pressure of 140 pounds per square inch. The angles of inclination of the wedges were equal to $8^{\circ} 45'$, and their surfaces were covered with sheets of copper well coated with tallow. On removing the check pieces, the wedges commenced sliding back slowly and uniformly by the gravity of the arch and centres, and the motion was checked and continued until the arch was left in equilibrio.

(18.) The following experiments were made on different metals sliding on each other, and in order to determine the effect of surface, the same piece of metal was placed in one case flatwise, presenting a surface of 44 inches, and in the other edgewise, having only a surface of $6\frac{1}{4}$ inches.

From the foregoing experiments it appears that the friction of

Cast iron upon cast iron laid flat, varies from	6.58	to	7.53
Cast iron upon cast iron laid edgewise.....	6.2		6.5
Hard brass upon cast iron laid flat	7.2		7.8
Hard brass upon cast iron laid edgewise	6.0		8.0
Yellow brass upon cast iron laid flat.....	6.09		7.22
Yellow brass upon cast iron laid edgewise ..	6.1		7.24
Tin upon cast iron laid flat.....	5.4		6.11
Tin upon cast iron laid edgewise.....	5.09		6.11

That the friction is nearly the same with cast iron and brass, whether the load be applied on the broad side or on the narrow side of the plates, although the areas of the surfaces are to each other as 6.22 to 1.

That tin being a softer metal and more easily abraded,

the friction increases when a load is applied above 8 pounds per square inch, but remains nearly the same with the broad side as with a narrow side. Generally speaking, the friction is less with the broad side than with the narrow side.

(19.) In the following experiments the object was to extend the preceding results to various metals, but without varying the surface. We have only attempted to give the extreme and mean results, but the entire Table may be advantageously consulted by the practical Engineer, as well as by the Philosophical inquirer. The weights moved, together with their load, varied generally from 14 pounds to 192 pounds. We have taken only those weights in which the proportions differed most from each other, and in a separate Table the several mean results.

Tin on cast iron	6.75	54.25	9.344	5.671	8 0.5

Upon the results of these experiments it is remarked,
1. That the friction of metals varies with their hardness.

2. That the hard metals have less friction than the soft ones.

3. That without unguents and within the limits of 32 pounds 8 ounces per square inch, the friction of hard metals against hard metals may very generally be estimated at about one-sixth of the pressure.

4. That within the limits of their abrasion the friction of metals is nearly alike.

5. That from 1.66 hundred weight per square inch to upwards of 6 hundred weight per square inch, the resistance increases in a very considerable ratio, being the greatest with steel on cast iron, and the least with

brass on wrought iron, their limits being as 30, 36, 38, and 44 hundred weight.

(20.) The following experiments were made with the view of determining the friction of axles. The apparatus consisted of a roller, with movable ends accurately turned, of three different metals, viz. cast iron, gun metal, and yellow brass; the pivots ran in bearings, truly bored in blocks of cast iron, leaving the axle full play, so as to prevent any binding; a cord was attached to the roller, which passed over a pulley, carrying a scale in which the moving weights were placed; the pivots projected beyond the bearing, and on these, slings were freely hung, which carried the scale, carrying the weights with which the axle was loaded. The greatest accuracy was observed throughout, the cord was the best sash line, and

the pulley very sensible; the whole descent of the body was only $4\frac{1}{2}$ inches, the time of descending is marked in the following Table.

Experiments on the friction of axles.

* In this experiment the axle had remained in a state of rest for forty-one hours, and it took 190 pounds to move it, but the axle being retouched with the composition, it required but 23 pounds 8 ounces.

Remarks on the preceding Tabular Results.

(21.) It appears when no unguents were employed, that when the gun metal was loaded with variable weights from 1 to 10 cwt., the friction varied within the limits of $\frac{1}{7.6}$ and $\frac{1}{4.7}$ of the pressure.

That the friction was greater with yellow brass than with cast iron, and the friction in all the three cases was reduced by using black-lead.

That when unguents were used with yellow brass and cast iron, the friction with the smaller weights was about one-thirty-seventh of the pressure, but with great weights of ten cwt. it increased to one-fifth or one-sixth.

That cast iron on cast iron under similar circumstances gave less friction, and still less when hog's-lard was substituted for oil.

That gun metal on cast iron gave less friction with hog's-lard than with oil.

The experiments with yellow brass on cast iron with anti-attribution composition gave very irregular results, but generally the proportion was greater with less weights than with greater weights.

That yellow brass on cast iron with tallow gave the least friction; this unguent is therefore to be recommended as the best in this case.

Manufac-
tures.

Yellow brass on cast iron with soap gave the next best result, and is therefore superior to oil

The worst result was with yellow brass on cast iron, and unguent soft soap and black-lead.

The general conclusion from all these seems to be, that the diminution of friction by unguents depends upon the weight and unguents conjointly; that the lighter weights require the finer and more fluid unguents, and the greater weights the contrary, as hog's lard, tallow, &c.

(22.) The following experiments were made to ascertain the effect of velocity on the amount of friction. For this purpose, a cast-iron roller was used, having bearings an inch wide at each end and six inches diameter, with a collar one-eighth of an inch deep, and the whole bearing surface twelve and a half square inches. A rope being wound round the cylinder, motion was communicated as in the last experiments. The whole descent of the weight was twenty-one feet.

The irregularity of the resistances in the first experiments without oil, particularly the first seven, is attributed to imperfect contact and grinding of the surfaces, but afterwards the roller having obtained its bearing, and the weight in the roller scale being diminished, the irregularity ceased.

From the results of these experiments it will be seen that friction did not increase with an increase of velocity, the time in falling the whole height being double the time in falling half the height with every velocity.

(23.) *On the friction of Machines.*—1. It appears that 21 hundred weight, suspended at each extremity of a chain passing over two cast-iron sheaves of 2 feet diameter with wrought-iron axles, working in brass bearings oiled, and 12 feet 10 inches apart, was disturbed by 3 hundred weight or one-fourteenth of the total weight. In another experiment on a double crane it appeared to require one-ninth.

2. A double-purchased crane having a weight of 7057 pounds suspended to it indicated 7.62 for the friction. Another double-purchased crane indicated one-ninth.

In an experiment made on one of the corn-mills recently erected for his Majesty's Victualling Department at Deptford, it required one-tenth of the weight of the mass to overcome the inertia and friction of the bearing and tangential surfaces. In this instance the pressures of the different parts of the Machine varied from 28 pounds to 8 hundred weight per inch area, and the velocities of the surfaces from 50 feet to 120 feet per minute.

From these experiments, several important conclusions may be drawn which cannot fail of being highly useful to the practical Engineer, and several doubtful points referred to in the beginning of this Essay seem fully cleared up; that friction is independent of velocity in nearly all practical cases is fully confirmed, notwithstanding what has been frequently stated to the contrary. It appears, also, that the allowance commonly made by millwrights of one-fourth of the pressure is considerably too great, except it be while the Machine is quite new, and while the different parts have not found their proper bearing.

(24.) *Rigidity of Cords.*—As cords and ropes are not perfectly flexible, it becomes necessary in estimating the real practical advantages of pulleys, capstans, &c., to make some allowance for this want of flexibility. Before a cord or rope can act in the manner supposed in theory a certain force must be employed to bring it into close contact with its pulley or roller, and to bring it into a straight line between the two points of application; and this force, whatever it may be, is of course lost as to useful mechanical effect, and ought, therefore, to be allowed for, when our object is to estimate the actual practical power of any Machine into which ropes and pulleys enter. Experiments have accordingly been made by different persons with a view of reducing this kind of resistance to determinate laws, as in the case of friction, but certainly without the same success. In the case of friction, whether proceeding from surfaces sliding on each other, or of axles turning in their brasses or bearing, there is always a sort of ultimate degree of perfection in the workmanship of the parts which is necessary to be attained, before we can hope to arrive at any thing like a law even in this case; but when it is attained, and considering the known and fixed character of the materials, a great similarity of effect may be expected. Unfortunately, this is not the case with cords and ropes, which, when of the best construction, differ greatly from each other in their rigidity, according to the quality of the materials of which they are composed, the matter sometimes used for their preservation, the degree of twisting to which they have been submitted, their dryness, or moisture, as depending upon their exposure to weather, and even according to the state of the atmosphere when they are not openly exposed; so that we can expect to obtain but little general practical information from experiments of this kind. It will be by far the safest

Manufactures. way, when the amount of rigidity is of importance to be known, to estimate it by experiments, at the time and on the actual rope or cord to be employed; and with a view of indicating the best way of performing such experiments, rather than with that of furnishing practical data, we propose to give a statement of one series of the experiments of Coulomb as given by him in vol. x. of the *Mémoires des Sçavans Etrangers*.

The method he pursued, which appears to be perfectly satisfactory, was as follows: having obtained two perfectly smooth and horizontal beds of timber, at a certain distance from and parallel to each other, he placed along them two rulers of hard wood well-planed, and across which was laid a well-turned roller; over this roller he hung several small packthreads whose rigidity might be considered as nothing; while thus balanced, an additional weight was added sufficient to give a very slight motion, and the amount of this weight was considered to exhibit

the resistance of the roller. He then repeated the experiment with the same weights but suspended now to different kinds of cord, and again ascertained the weights requisite to give the same degree of motion as before, and he then assumed that the difference of the two weights in the two cases was the proper measure of the cord's rigidity; and certainly for those particular ropes there can be no question respecting the assumption. The cords employed were of three kinds: No. 1. 6 threads in a yarn, or 2 in a strand, the circumference $12\frac{1}{2}$ lines, weight of a foot in length $4\frac{1}{2}$ drachms. No. 2. 15 threads in the yarn, or 5 in the strand, weight of a foot in length $12\frac{1}{2}$ drachms, and circumference 20 lines. No. 3. 30 threads in a yarn, or 10 in a strand, circumference 28 lines, and weight of a foot $24\frac{1}{2}$ drachms. The diameter of the different rollers and their weight and quality are stated in the following Table.

Machinery.

Experiments on rigidity of cords.

There can be no doubt of the accuracy with which these experiments were performed; and no better means can perhaps be devised for ascertaining the amount of rigidity in any other cases; but we must again repeat that little or no practical advantage can be derived from the results, in consequence of the great uncertainty attending the amount of rigidity in different ropes; the experiments have therefore been given rather as pointing out one of the best practical methods of determining the amount of rigidity where it is required to be known, than as furnishing data for making allowances in any particular mechanical constructions.

In many cases it is not necessary to know the amount of rigidity independent of friction, the sum of the two being all that is requisite. Thus in the experiments we have already given by Mr. Rennie on friction, it was necessary for him to know what was the amount of friction and rigidity together, and not separately, in the pulley and rope by which his descending weight was attached, this part being altogether distinct from that friction of which he was endeavouring to ascertain the amount; and he accordingly determined the amount of this portion of the whole, by suspending equal weights on each side the pulley, and then ascertaining the weight requisite to give to the system an incipient motion, and from these results the proper deductions were to be

made in estimating the amount of friction on the other part of the system.

(25.) *On the effect resulting from the application of motive and retarding forces to Machines in motion.*—It has been shown in the preceding sections from the highly satisfactory experiments of Mr. Rennie, that the intensity of resistance to the motion of a Machine from friction, is independent of its velocity; and it hence follows, that the retardation to motion arising from this source may be combined with that arising from the resistance experienced at the working point, and that after such combination, and after the motion of the Machine has become uniform, the momenta at the impelled and working points must be equal to each other. Now the momentum at the working point is equal to the force or motive power into its velocity, that is equal to Fv . Here, however, Fv represents the power of the agent, and in many cases a part of this power is expended either in giving motion to the agent itself, or in giving motion to certain inert matter which acts upon and is external to the Machine to which motion is to be communicated. The first case comprehends the action of a spring, which, in order that it may exert any force or give motion to a Machine, must first unbend itself, and by so much force as this requires will its effective force on the Machine be diminished. And the second includes the

of motive
and retard-
ing forces
on Ma-
chines.

case of Gravity acting on a descending weight, which weight must first be put in motion before it can give motion to the Machine, and hence the necessity of considering its inertia. The case, however, which is most obvious is when the muscular power of a man or other animal is the first mover; such, for instance, as a man pushing at a capstan bar. In this case, the man must first walk as fast as the bar moves round, and this requires a certain expenditure of his muscular force; but this alone will not render his action effective: he must also push forward the bar with what force he may have remaining over and above what he expends by walking at that rate; and the proportions of these two expenditures of force may be very different in different cases, according to the load to which he is exposed, or the velocity with which he moves. In fact, the useful result of a man's action, or that of any other animal, depends upon the weight moved, the velocity with which it is moved, and the time he can continue his exertion during a given interval, as a day, a week, or a month; so that here another term is necessary to be introduced. Calling, therefore, the weight moved w , the velocity v , and the time the man can continue his exertion t , we have wvt as the useful effect. Now it is obvious that if w is so large that the man has not power to overcome it and put it in motion, we must have $v = 0$, and consequently also $wvt = 0$, that is no useful effect will be produced, although the whole force of the man is employed and exhausted. Again, if v is so great as to require all his power to preserve it, he will not be able to move any load; so that here $w = 0$, and consequently $wvt = 0$. And if the product vw , or the velocity with which he moves, and the weight he moves, are each large; then t , if it does not entirely vanish, may become so small as nearly to reduce the effect again to zero. Seeing then that there are two actual cases in which the effect becomes zero, and one in which it approximates closely to it, whereas the whole effect increases as we recede from these extreme cases; it is obviously a highly important consideration for the Engineer to determine the proper values to be given to w , v , and t , in all cases, so that the maximum effect may be produced, either by means of theory or by practical experiment; and by the latter rather than by the former, these proportions have been determined for the action of men and horses. (Art. 4.)

We have selected this case of animal action to illustrate our remarks, but similar considerations, modified according to circumstances, attend the application of all first movers. In the case of animal exertion, we are limited by the amount of muscular power, velocity, and time; in other cases time does not enter, because natural powers may be continued indefinitely without weakening their efficacy; but other limitations step in. As for example, in a Water wheel, it is obvious we can only make the wheel move as fast as the stream; but if we make it move so fast, it is evident that no force remains to overcome any resistance; therefore, the useful effect is nothing, and the same will be the case if we oppose such a load that the stream is not able to overpower it, so that the water escapes unproductively; in this case no velocity ensues, and the effect is again nothing. It becomes, therefore, a question what resistance we ought to oppose to produce the most useful effect. Theory makes it one-third the velocity of the stream, and experiment, if it does not confirm this result, proves that the velocity must not differ greatly from this quantity. (Art. 9.)

In the Windmill the limitation arises from another Machinery cause. The quantity of surface being given, the effect will depend upon the angle at which the sails are placed, and the pressure upon them will be greatest when they are placed perpendicularly to the direction of the wind: but then there is no tendency to produce rotation, nor is there when they are placed parallel to the direction of the wind; some intermediate angle, is, therefore, to be determined, and theory gives that angle $50^{\circ} 40'$. But according to the experiments of Mr. Smeaton, although that angle gives very nearly the greatest velocity when the mill is unloaded, it does not produce the greatest effect when the load is on. The best angle, according to practice, seems to be about 72° .

In the Steam-engine we seem nearly free from all limitations; it is true, the action of the steam on the piston is diminished by the speed of the piston itself, but the velocity with which such an elastic fluid as steam rushes into a vacuum is so great, that the velocity of the piston is incomparably small in respect to it, and the limitation does not, therefore, lie there; but the nature of the engine itself steps in; we are limited by convenience to the length of the stroke, and to the velocity by the loss sustained by reciprocation, and other circumstances, so that here, also, a certain speed has by long experience been found to be better than any other for useful effect; and that speed, according to the practice of the best masters, is about 220 feet per minute.

These remarks apply to the application of the first mover of a Machine to the impelled point, or to what may be called the second mover. Velocity or rotation being obtained in this, it may be transmitted by means of interposed machinery to the working point, with a velocity the same as that of the impelled point or greater or less in any proportion. As far, therefore, as equality of motion is concerned, we may give any velocity to the working point; but here again attention must be paid to the nature of the resistance to be overcome, or which the work to be performed opposes to the action of the Machine.

Sometimes the work opposes not a simple obstruction, but a real resistance of reaction, which, if applied alone to the Machine, would cause it to move backwards, or the contrary way to that in which the power directs it; this is always the case where a heavy body is to be raised, or a spring to be bent or compressed, and in some other cases. In others, there is no such reaction, but merely obstruction: a flour-mill, a boring-mill, a saw-mill, and many other engines exhibit no reaction of the former kind; but although such Machines when at rest, or when not impelled by the first mover, sustain no pressure in the opposite direction, yet they will not acquire any motion whatever, unless they be impelled by a power of given intensity; any less force leaving them perfectly inactive. Thus, in a saw-mill, a certain force must be impressed upon the teeth of the saw, in order that the cohesion of the fibres of the timber may be overcome. This requires that a determinate force depending on the proportions of the Machine be impressed on the impelled point. Now, if this and no more be applied there, the cohesion of the wood will be only just balanced, and motion will not ensue; but if any additional force be impressed on the impelled point, the cohesion of the wood, before only just balanced, will now be overcome, and work will be performed. It is obvious, therefore, that it is only this additional force that is effective as

Manufactures. to useful mechanical agency, all the other being merely engaged in balancing the cohesion of the woody fibres. We may then, while the Machine is at work, consider it as acted upon by two forces, one urging it forward at the impelled point equal to the whole force employed, and another at the working point, acting in an opposite direction, and equal to the whole resistance furnished by the work. It is to be observed, also, that it is not merely the resistance offered by the work which the impelling force is required to overcome, it is necessary that it should overcome the inertia of all the moving parts between the impelled and working points, and the friction of all the rubbing surfaces; that is, before the necessary force can be exerted at the working point, the various connecting forces must be exerted in the different parts of the Machine; and in order that the working point may follow out the impression already made, all the connecting parts of an engine or the limbs of an animal must be moved in different directions and with different velocities; consequently, force is continually employed to produce these changes, which is altogether inefficient at the working point, being, as it were, absorbed and lost in its transit; and precisely the same remarks apply to the resistance produced by friction. Time, also, must elapse before all this can be accomplished; and in reciprocating motions in particular, a great deal both of power and time are thus consumed. Even in some which are not called reciprocating Machines, a great waste is frequently occasioned. Thus the walking crane, worked either by men or animals, acquires motion, in consequence of the inertia of the wheel, by very slow degrees; but at length the load is raised, the whole matter now in motion is to be stopped, which must also be done by degrees, because to stop it suddenly would not only shake the whole structure, but throw down the men or animals; again the motion is to be reversed, the Machine again brought to rest, and so on, obviously rendering such an apparatus very inconvenient and disadvantageous for the purpose designed. The same thing occurs, although in a less degree, in a steam-engine, where the beam and pump-rods, sometimes weighing many tons, must be made to obtain a considerably rapid motion in opposite directions twice in every complete stroke; and it must of course obtain in a greater or less degree in all engines which have a reciprocating motion in any of their parts; hence reciprocation unnecessarily introduced into any Machine is injurious, and is always avoided by the judicious Engineer.

In the application of first movers to the impelled point of Machinery, from the limited number of agents employed for this purpose, we are enabled to examine all the cases, both theoretically and experimentally, and to arrive at certain fixed principles; but in the application of the working point to the duty it has to perform, this is actually impossible. This duty may be to polish a button or to work a forge hammer of some tons weight, to grind corn, to express oil, to spin cotton, or a thousand other processes in which the questions of speed and resistance assume every possible variety of character. It would be, therefore, a mere affectation of accuracy, and tend to the degradation of Mathematical principles, to attempt to call in their aid in such cases. It is true that by assuming the amount of all the resistances, including friction, to be equal to a certain weight appended to the working point, we may reduce

VOL. VII.

Machinery. the question to a Mathematical form, and arrive at conclusions carrying on the face of them every appearance of accuracy; for the difficulty is not in the transformation of the formulæ, but in fixing the data, and as it is impossible to do this with any degree of certainty, we will not, notwithstanding the example of others, enter into any calculation on these subjects. We have considered it right to call the attention of the reader to the nature of the difficulties a Machinist has to contend with, and the views by which he ought to direct his steps in the application of the power to the work to be performed, but we will not attempt to point out to him rules for carrying his object into execution, where no certain rules can be given, and where so much must rest with his own judgment, means, and conveniences, and the certain and valuable knowledge which nothing but practical experience can bestow.

OF THE ELEMENTARY PARTS OF MILL WORK, AND THEIR CONSTRUCTION.

(26.) Before we enter upon the general description of Mill work mills under their various forms, it will be proper to treat of definitions, their detached parts, and to define many of the technical terms by which different parts are distinguished from each other,

Wheels. The general signification of the word wheel is sufficiently understood. As far as regards our present subject we have only to consider, here, those which are employed in mill work, for the purpose of communicating motion. These are *toothed wheels, cog wheels, spur wheels, face wheels, bevelled wheels, &c.*

A *toothed wheel* is generally understood to be one in which the teeth are cast or cut on the wheel itself, forming one whole.

A *cogged wheel* is one in which the teeth are supplied by pieces of iron or wood, commonly called cogs, not formed with the wheel, but inserted in its periphery, or on its face.

A *spur wheel* is one in which the teeth or cogs are on its periphery, and the term is thus applied, from the resemblance the wheel has to the rowel of a spur, the teeth taking the direction of radii.

A *face wheel* is one in which the teeth or cogs are placed round its periphery, parallel to the axis of the wheel; these were formerly very commonly employed for the purpose of producing a motion at right angles to its own; but this is now generally done by means of what are called bevelled wheels or bevelled gear.

Bevelled or mitre wheels have their teeth formed upon a conical surface, the angle of the cone depending on the angle which the axles of the two wheels make with each other; the introduction of this class of wheels into Machinery, is a comparatively recent improvement: they of course are always employed to work with others of the same form.

When two toothed wheels of different sizes work together, the largest is commonly called the *wheel*, the other being denominated the *pinion*.

Sometimes the pinion takes the form shown in fig. 8, Plate i. plate i., that is, a number of round staves are placed between two wooden or iron circular ends. It is then termed a *trundle*, sometimes a *lantern* or *wallower*.

A *fly wheel* is a large heavy disc or rim of iron, attached to some revolving part of a Machine, to give uniformity of motion.

The teeth and cogs of wheels, pinions, &c. are frequently comprehended under the term teeth; notwith-

Manufac-
tures.

standing, when speaking with precision, those only are teeth which form a part of the wheel itself: the others, as we have already stated, are properly called cogs.

The teeth of pinions are also distinguished by the term *leaves*, and those of the trundle by *staves* or *rounds*.

The axle on which a large wheel is fixed, is called a *shaft*; but those on which smaller wheels are attached, are called *spindles*. When shafts lie in a horizontal direction, they are called lying or horizontal shafts; when vertical, they are denominated upright or vertical shafts.

The part which supports a shaft, or in which it revolves, is termed a *carriage*, when it is part of the framework; when detached, it is usually termed a *plumber block*, a supposed corruption of *pillow block*. When a horizontal shaft has a support, between the points at which the power and resistance are applied, and on which it turns, the part of the shaft which revolves on this support is called a *journal*.

The bearings for pivots or gudgeons, at the lower extremity of upright shafts, are denominated *steps*, and the parts where the journals of vertical shafts, or spindles turn, and bear against, are called *bushes*; the smaller sort, however, are commonly denoted by the word *breasts*.

Shafts are made of wood or iron; when of wood, they must, necessarily, be terminated by short iron axles, and these axles are termed *gudgeons*; the forms of which, as now generally made, will be hereafter described.

In Machinery it is sometimes necessary to convey motion to a greater distance than can be done by a single shaft; when this is the case, two or more are connected together, and this connection is called a *coupling*: when the coupling is effected by a box, into which the ends of the two shafts fit, this box is termed the *coupling box*; when there is no box, they are called *clutches* or *glands*.

Having thus defined, in general terms, the distinction which workmen have given to some of the more common parts of mill work, we must proceed to describe those parts more minutely, and the rules which must be observed in their construction.

Teeth of
wheels.

(27.) *Of the teeth of wheels.*—The figure of the teeth of wheels, is obviously a subject of great importance, and is reducible to exact Mathematical principles, and has, accordingly, engaged the attention of several very distinguished Mathematicians, from whom, as well as from ingenious practical men, many very useful principles have been introduced; some of which are described below. But here again, in order to understand the directions properly, a few definitions are required. When two wheels are working together, the number of the teeth being fixed upon, the line joining their centres is called the *line of the centres*, and if this line be divided in the ratio of the number of the teeth in each wheel, this point limits what is called the *pitch line* or *circle*; viz. a circle being described from each centre, passing through this common point, it will give two circles, and the diameters of these are called the primitive or *proportional* diameters, and the circles themselves the *pitch lines*, and the *pitch of the teeth* is the distance of them from each other, as measured across this line, as a chord, not along its circumference. These terms being explained, it will not be difficult to comprehend the direction for the form of teeth, as given below; in which we have avoided, as much as possible, every unnecessary Mathematical refinement; which has not, perhaps, in this particular case, been so advantageously employed as in many other inquiries.

It has been, indeed, demonstrated by Camus, Emerson, Young, and other eminent men of Science, that the best form of teeth is, when they take the figure of an epicycloid; but in this determination some points of practice are overlooked, and the present most general method is, to make them arcs of circles, and by increasing, as far as can be, their number, and making two or three act at the same time, a smoother and more equable pressure is maintained than could easily be effected with larger teeth, constructed according to the most accurate Mathematical rules. The equalization of motion is also still further produced in some wheels, by having two, three, or four rows of teeth on the same surface, succeeding each other uniformly, so as to ensure the continuous action of several teeth, and thus increasing the number of bearing points.

Some difference of shape is requisite, accordingly as the wheel acts against, or is acted upon, by the staves of a trundle, or the leaves or teeth of a pinion. When the wheel acts against the cylindrical staves of a trundle, Mr. Tredgold, in his edition of Buchanan's Mill Work, recommends the following construction:—

(28.) Let CD, plate i, fig. 1, be the line of centres, EE the pitch line of the trundle, and FF that of the wheel, and suppose the centre of the stave A to be in the line of centres CD; place one foot of the compasses in the centre of the stave A, and describe the arc *b c*, which is the form of the tooth. The part of the teeth of the wheel within the pitch-line may be described with circular arcs, as in the figure. The reader will easily perceive that the radius for describing the teeth is equal to the pitch, diminished by half the diameter of the stave; and also, that the centre of those arcs will always be in the proportional circle or pitch line of the wheel.

Some authors have imagined that the friction of the wheel and trundles might be reduced by making the staves revolve, but it could not be effected so far as to balance the extra labour of construction, and where the strain would be considerable, it would become quite impracticable.

Smeaton appears to have been very partial to the wheel and trundle, when the trundle was executed with cast-iron staves, which he recommended to be of an oval figure, and made smooth by grinding. It may be demonstrated, that the least real radius of the wheel should be equal to the proportional radius, added to half the pitch, when the necessary allowances are made for wear, and when the staves are of the same diameter as the thickness of the teeth. But when the staves are larger than the teeth, as in the figure, a less real radius is required.

(29.) Buchanan, in his Treatise on Mill Work, gives the following rules for forming the teeth of a wheel and pinion:—

Having set off upon the proportional circles, fig. 2, the points G Q L and O o H, according to the thickness of the teeth and leaves, draw lines from these points towards the centre of their respective circles, to serve as the sides of the spaces between the teeth and between the leaves; the depth of which spaces must be such as to give room for the action of the curved part of the teeth and leaves. Then describe upon the extremities of the sides of each tooth, epicycloids, such as Q D. L D, with the generating circle Y, the diameter of which is equal to the proportional radius of the pinion, upon the circumference of the proportional circle of the wheel as a base. The mode of forming the teeth being

tures.

thus shown, that of the leaves will be obvious; vv being the generating circle of their epicycloid, upon the circumference of the circle of the proportional pinion as a base.

(30.) When the teeth are small and do not begin to act till they arrive at the line of centres, the teeth of the wheel when the wheel drives the pinion, or the leaves of the pinion when the pinion drives the wheel, may be described by a circular arc, of which the radius is equal to the pitch, and of which the centre is in the pitch line of the wheel or pinion.

This method will always enable a workman to execute short teeth nearer to the true form, than any pattern tooth will enable him to do. Pattern teeth and compound curves are things that may, on some occasions, be useful: where the teeth are long and of considerable magnitude in respect to that of the wheel or pinion to which they belong. But in all the ordinary forms of wheel work, such operations must consume an immense quantity of valuable labour, to attain even the same degree of accuracy that is at once obtained by means of circular arcs.

Fig. 3.

In order to effect this, a method which is extremely simple is explained in fig. 3. The wheel being made, and the cogs fixed in much larger than they are intended to be, a circle AA is described upon its pitch diameter, and the circle BB is described within the pitch-line, for the bottom of the teeth, and a third, DD , without it, for the extremities. After these preparations, the pitch-line is accurately divided into the number of teeth the wheel is intended to have; a pair of compasses is then set to the extent of one and a quarter of these divisions, and with this radius arcs are struck on each side of every division, from the pitch-line A to the outward circle DD . Thus, the point of the compasses being set in the division e , the curve fg on one side of a cog, and no on one side of another, are described; then the point of the compasses being set on the adjacent division k , the curve lm is described, which completes the curved portion of the cog e ; and the same may be done all round, for every cog. The remaining portion of the tooth within the pitch-line AA , is bounded by two straight lines, drawn from the points g and m towards the centre, as described in the former method. This being done all round, the wheel is set out, and the cogs being dressed or cut down to the lines, will be formed ready for work, every cog being of the same breadth, and the space between every tooth and its adjacent one is exactly equal to the breadth, provided the compasses are open to the extent of one division and a quarter, as first described.

Fig. 4.

(31.) Other methods of forming teeth have been proposed; among them the following. Let the tooth a (fig. 4) press on the tooth b , in the point c , and draw the line $FCD E$, perpendicular to the touching surfaces, in the point c ; draw $AFBE$ perpendicular to FE , and let FE cut the line AB in D . It is plain, from the common principles of Mechanics, that if the line FE , drawn in the manner now described, always pass through the same point C , whatever may be the situation of the acting teeth, the mutual action of wheels will always be the same. But this construction is subject to a limitation, which must not be neglected. The teeth must be so made, that the curved part of the tooth b is acted on by a flat part of the tooth a , till it comes to the line AB in the course of its action; after which, the curved parts of a act on a flat part of b , or the whole action of a or b is either completed or only begins at the line AB , joining the centres of the wheels.

(32.) The following form of the teeth secures the perfect uniformity of action, without this limitation, but it requires very nice execution. Let the teeth of each wheel be formed by evolving its circumference; that is, let the acting face GCH of the tooth a , have the form of a curve traced by the extremity of the thread FC , unlapped from the circumference. In like manner, let the acting face of the tooth b be formed by unlapping a thread from its circumference. It is evident that the line FCE , which is drawn perpendicularly to the touching surfaces in the point C , is just the direction of position of the evolving threads, by which the two acting faces are formed. The line must, therefore, be the common tangent to the two circles or circumferences of the wheels, and will, therefore, always cut the line AB in the same point D . This form allows the teeth to act on each other, through the whole extent of the line FCE , and therefore will admit of several teeth to be acting at the same time. This, by dividing the pressure among several teeth, diminishes its quantity on any of them, and therefore diminishes the dents or impressions which they unavoidably make on each other. It is not altogether free from sliding or friction, but the whole of it can hardly be said to be sensible. The whole side of a tooth, three inches long, belonging to a wheel of ten feet diameter, acting on the tooth of a wheel of two feet diameter, does not amount to one-sixtieth of an inch, a quantity altogether insignificant.

Before leaving this subject, it will be well to describe a mode proposed by Mr. Tredgold for the construction of the teeth of two wheels, or a wheel and pinion to act with each other, in which he makes the teeth of the small wheel or pinion to represent the staves of a trundle. Let the teeth be divided as usual on the pitch-lines EE , FF , fig. 5, and on the conducted wheel C describe circles, as though they were to be staves. Conceive the centre of one of these stave teeth to be in the line of centres at A , and draw the line AB , joining the centres of the stave teeth. Then the radius Ab from the centre A will describe the curved side bc of the tooth of the conductor, and the curved part ba of the conducted wheel: and since this radius is equal to the pitch, diminished by half the diameter of the circle of the stave teeth, and as the centres will always be in the pitch-line of the wheels, all the other teeth may be easily described.

Fig. 5.

(33.) Conical wheels or bevel gear may be considered as consisting of two cones, rolling on the surface of each other: thus CD and DE , fig. 6, may be conceived to be the bases of two cones, turning on their centres, having teeth cut on them, diverging from the apex B to the bases CD and DE , but the teeth near the point of the cone being small and of little use, may be cut off at G and H . These teeth may be made of any breadth, according to the stress they are intended to bear, and this is of great importance, because by this method they may be made to overcome a much greater resistance, and work smoother than a face wheel and trundle of the old form. Besides these kind of wheels are of singular use to communicate motion in any direction, or to any part of a building, with less trouble and friction than wheels of any other construction.

Construction of the teeth of bevelled wheels. Fig. 6.

The action of the teeth of bevelled gear is exactly similar to that of common spur wheels, the diminution of the teeth towards the apex of the cone being in the same ratio in both wheels, and consequently, the same form of teeth, already described, may be adapted to

Manufac-
tures.

them. The construction, however, becomes a little more difficult: let C D, fig. 6, be a bevelled wheel, being a portion of the cone C B D, and A B its axis. Let the cone A C D be described reciprocally or having its slant height at right angles to C B D, it is evident that this cone will intersect the teeth at right angles, and consequently, that the true figure of the teeth may be represented on its surface. It may also easily be seen that the surface of this cone may be developed on a plane, by rolling it round its apex A as a centre, and that the true impression of the teeth will be thereby made. The pitch circumference C D will of course be the sector of a circle, having the slant height B C as radius.

The reverse operation then may be made use of in the construction of the teeth of bevelled gear, and Mr. Tredgold recommends that two or three pattern teeth, made in copper or any other flexible material, be in this way constructed for the larger and smaller end of the teeth.

Strength of
teeth of
wheels.

(34.) Having above described some of the most practical methods of obtaining the form of teeth, it may be proper to offer a few observations on the strength they ought to possess according to the power and resistance they have to oppose. This, however, is a simple question, for the pressure being on the pitch-line, the teeth may be considered as a beam fixed at one end sustaining a pressure at the other, therefore the length, breadth, and depth being given, the strength may be found by the principles already explained in the article on the strength of materials in our Treatise on MECHANICS, and when the pressure, and the length and thickness of the tooth are given, its breadth may be found by the following rule, when the material is cast iron.

Multiply the pressure at the pitch-line by the length of the tooth to this line in inches, and divide the product by 2544 times the square of the thickness, and the quotient will be the breadth in inches.

Thus, if the pressure at the pitch-line of a wheel is 6000 pounds, the thickness $1\frac{1}{2}$ inches, and the length 3 inches. Required the breadth.

$$\text{Here } \frac{6000 \times 3}{2544 \times 1.5^2} = 3.14 \text{ inches the breadth.}$$

It is seldom, however, that such a calculation is requisite, as generally the breadth of the teeth far exceeds what is required for mere strength. The best millwrights commonly make the breadth of the wheel and teeth about two or three times the pitch of the teeth.

(35.) The following Table is given as a specimen of the pitch and dimensions of teeth as deduced from several wheels which are actually constructed and performing satisfactorily; the horse-power and the velocity per second are also stated.

Table of the Pitch and Dimensions of Teeth, with the Horse-powers to which they are opposed.

Pitch of teeth in inches.	Thickness of teeth in inches.	Breadth of teeth in inches.	Length of teeth in inches.	Horse-power at 2.7 feet per second.	Horse-power at 3 feet per second.	Horse-power at 6 feet per second.	Horse-power at 11 feet per second.
4.2	2.	8.	2.40	13.33	17.61	35.23	64.6
3.99	1.9	7.6	2.28	13.03	15.90	31.80	58.30
3.78	1.8	7.2	2.16	10.80	14.27	28.54	52.32
3.57	1.7	6.8	2.04	9.63	12.72	25.54	46.68
3.36	1.6	6.4	1.92	8.53	11.27	22.54	41.32
3.15	1.5	6.	1.80	7.50	9.91	19.82	36.33
2.94	1.4	5.6	1.68	6.53	8.63	17.26	31.64
2.73	1.3	5.2	1.56	5.63	7.44	14.88	27.28
2.52	1.2	4.8	1.44	4.80	6.34	12.68	23.22
2.31	1.1	4.4	1.32	4.03	5.32	10.64	19.54
2.10	1.	4.	1.20	3.33	4.40	8.81	16.15
1.89	.9	3.6	1.08	2.70	3.57	7.14	13.09
1.68	.8	3.2	.96	2.13	2.81	5.62	10.33
1.47	.7	2.8	.84	1.63	2.15	4.30	7.88
1.26	.6	2.4	.72	1.20	1.59	3.18	5.83
1.05	.5	2.	.60	.83	1.10	2.20	4.03

It will be observed that the prevailing proportion in this Table is, that the pitch is 2.1 times the thickness of the tooth, and the length 1.2 times the thickness; but different masters differ considerably in these proportions, so that no very determinate rule can be given.

(36.) The relation between the primitive or proportional radii of wheels and the number and pitch of their teeth is, however, determinate, and Mr. Bryan Donkin has published a little Table, showing the several radii of wheels having a pitch of 2 inches, from 10 to 300 teeth, which is very useful; this Table we have reduced to an inch pitch, and by this means it becomes, we conceive, rather more simple. It is only necessary in this case to multiply the numbers standing in the Table opposite any number of teeth by the proposed pitch of a wheel, and the product will be the primitive or proportional radius, that is, the radius measured from the centre to the pitch-line.

The principle on which the Table is founded is obvious. If we divide 360° by twice the number of teeth, it will give half the angle the pitch subtends at the centre, and the cosecant of this angle to a radius equal to half the pitch is obviously the radius sought; we may, therefore, exhibit the rule in the following general formula:

$$\text{primitive radius} = \frac{1}{2} p \times \text{cosec } \frac{180^\circ}{\text{number of teeth.}}$$

In the following Table $p = 1$, therefore, for any other case multiply the tabular number by the pitch for the radius required.

Note. For any greater number of teeth than is given in the Table, it will be sufficiently accurate to work as for half the given number, and double the result; but for any number less than 10, it will be best to have recourse to the general formula.

Construc-
tion of cog
wheels.

Fig. 7.

Fig. 8.

(37.) *Construction of Wheels.*—Cog wheels were formerly made of wood, and some are still constructed of that material; but of late years cast-iron wheels have been substituted, and found much superior in strength, accuracy, and durability. Wooden wheels are framed together in segments usually of three thicknesses, to break joint upon each other. (See fig. 7.) The middle thickness is made in six or eight pieces, and left on the inside with straight sides, *aa*, into which the arms are fitted and bolted. On each side this middle thickness another, *bb*, is placed, with break joints, and all the three are bolted together to make a solid rim, into which the cogs are to be fixed by mortises, the tenons or tails of the cogs being held in their places by a pin driven through each. The arms of wooden wheels are made in different ways; sometimes they are mortised through the shaft, and the ends are notched in the middle of the sides of the pieces *aa*, and bearing against the face of them behind, where they are bolted to them to make all fast. This manner of uniting the arms with the rim is shown at *l*, (fig. 8,) but it is not the best, because the mortises weaken the shaft very materially, and it is diffi-

cult to get such a wheel off, if ever it be required on the failure of a shaft, &c. on this account a method of doing it by what is called clasp arms is much preferable; it is shown in fig. 7. Here four arms are used, which are halved into each other, and form a frame as in the figure, leaving a square opening in the centre, and holding the rim of the wheels by their ends, which are bolted to the middle thickness of the rim, as shown in fig. 8. To fit on such a wheel as this, the shaft is made up to a square by fixing pieces of wood upon its sides, and the wheel being hung upon this is made fast by wooden wedges driven in all round; the square formed between the arms being rather larger than the shaft, by this means the wheel can be adjusted to become quite true by the wedging. Face wheels, like fig. 8, have sometimes stays or braces proceeding from the back of the rim to some distance along the shaft, where they are received in mortises, as shown by the dotted lines; these make the wheel exceedingly strong, and keep it very stiff in the square upon its axis, which is very necessary, as the action of the teeth of a face wheel with a trundle is to throw the wheel back upon

Manufac-
tures.

its shaft, which tendency these stays effectually counteract. Sometimes two sets of clasp arms are used for the same purpose, one bolted on each side of the middle thickness of the wheel by the same bolts which pass through both as well as the wheel, and unite the two sets like one of considerable depth, so that the wedging will have greater effect to keep the wheel in the square. Small wheels are frequently made of plank, solid without any arms. In this case, the middle thickness is made of four pieces, leaving a square hole between them, and they are kept together by a circular rim of segments bolted on each side all round, and the joints overlapped. The construction of trundles requires little illustration, except that they usually have an iron hoop fitted round the circular boards to prevent them from splitting. Small pinions are made out of one block of wood, and the cogs are fitted into it, much in the same way as the spokes are let into the nave of a coach-wheel.

Iron
wheels.

(38.) Iron wheels have either the teeth cast in the same piece with themselves or mortises are left in the rim for the reception of wooden teeth, according to the purposes to which they are intended to be applied. Cog wheels are found to work with less friction and noise when one has wooden and the other iron cogs. In this case, the thickness of the wooden cogs is made to exceed a little the space between them, about one-tenth of the thickness of the cog, while in the corresponding wheel the space in the same degree exceeds the thickness of the teeth. The smaller wheel is usually made with the iron teeth, and the larger one with the wooden ones. Hornbeam is found to be the best wood for the cogs, as it is not liable to split or splinter away by long wear, and is capable of taking a very smooth surface. Cogs are secured in their places by a tenon or pin driven in the inner side of the rim of the wheel. They are made larger than their final dimensions, and are dressed when on the wheel to the proper size and shape in the same way as is described for wooden wheels. Iron cogs are usually first chipped with a cold chisel and hammered to near the figure, and then filed true. Some Machinists, however, dispute the propriety of dressing iron cogs at all; they say that the exterior surface of the casting has a kind of case hardening, which is thus removed, and a softer substance of metal exposed to the acting surfaces. This is true, and the objection would have its full force, if it were possible to make castings perfectly circular, and all the cogs precisely of the same size; but as our present skill in casting iron cannot insure this, it is better to chip and dress the cogs; accuracy in the form of the teeth being a greater consideration than the quality of their substance.

Fig. 9

When iron wheels do not exceed the size of eight or ten feet, they are cast in one piece, but beyond that size there is great liability to fracture in the cooling, in consequence of the arms having a less body of metal than the rim; they therefore cool sooner, and by their contraction either separate from the rim, or bring a strain upon it which will warp it out of its true figure, and at the same time give a constant tendency to fracture upon the slightest blow or jar. For this reason the arms in larger wheels are cast separate from the rim, and attached to it by means of a flanch, which is bolted to the inner rib or flanch of the rim, as shown at *a*, (fig. 9,) which is a representation of the halves of two wheels, one being cast solid, and the other with the arms separate from the rim. When wheels exceed the size of twelve or fourteen feet diameter, it is necessary to cast them in

a greater number of pieces, as at this size the parts become so unwieldy, as not only to be difficult to mould, but inconvenient from their weight and size to fit together. The mode of connecting the parts of wheels of the larger size, viz. from fourteen to twenty and twenty-four feet diameter, is a matter of considerable difficulty, and one in which the best masters disagree. That which is most adopted, and generally considered the best, is represented in fig. 10, where the wheel is cast in five parts, the arms being in two and the rim in three. One wooden pattern serves for the three castings of the rim, and one for those of the arms. The arms are bolted together at the nave or boss by means of two lugs or projecting pieces cast upon it, *aa*, and sometimes further secured by wrought-iron hoops, *bb*, which fit into a groove cast in the boss to receive them. They are joined at their extremities to the rim in the same way as described in the last method. The portions of the rim are united by flanches cast upon their extremities at right angles to their circumference, which are bolted to similar ones in the corresponding part, as shown at *c* in the figure. Upon one of the flanches at each joint of the rim, projecting pieces, termed by millwrights *chipping pieces*, are left, by means of which they are fitted and adjusted to each other; without such pieces the fitting of the whole surface of a flanch would be a work of much difficulty and labour. Fig. 11 represents another mode of arranging the parts of a wheel, which, however, is never made use of but in those of very large dimensions. In this the boss is cast in one piece, with short arms terminated by a flanch to which the arms of the wheel are bolted. The arms are cast in three or four pieces, according to the number the wheel is intended to have; the casting consists of one arm, *AA*, and the halves of the two *BB*, *CC*, and is connected with them at the lower extremity by a flanch *DDD*, which is fitted and bolted to the corresponding one in the centre piece. The half arms are bolted to each other along their length as shown at *aa*, and are secured to the rim in the same way, as has been described for the other methods.

In some situations it is necessary to attach a wheel to a shaft which is in its place, and cannot conveniently be removed. In such cases, however small may be the diameter of the wheel, it is necessary to cast it in two halves, the same pattern serving for both castings. The two parts of the wheel may be joined at the rim and boss by the method shown in fig. 10, or by bolting them along the arms.

(39.) *On the method of hanging wheels.*—The manner of attaching or hanging wheels upon their shafts, is an operation on the accuracy of which greatly depends the perfection of mill work. Wheels are generally fixed upon their shafts or axles before the teeth are set out, or if this be not convenient they are fixed upon a temporary shaft for the purpose. Wooden wheels are usually attached to a temporary shaft, which revolves in its bearings, and by means of tools applied to the circumference they are turned to a true circle, or if they differ much from truth, a circle is marked upon the rim to which they are afterwards reduced. The circumference is then divided, and mortises are cut out for every cog, which are larger than they are intended to be, that they may be set out as above described, and reduced to their true figure without absolutely depending upon the accuracy of the mortise cut to receive them. Iron wheels, as before mentioned, are treated in a different manner; being cast in the mould of a truly circular pattern, made of

Machinery.

Fig. 10.

Fig. 11.

Hanging
wheels.

Manufactures.

wood; the cogs being cast solid with the rim, or otherwise mortises left all round for the reception of wooden cogs; in either case the rim is a true circle, and must be fixed upon the shaft exactly by its centre, instead of forming the circumference to the centre, as in the case of wooden wheels. In order to effect this, the centre hole through the iron wheel is made somewhat larger than the shaft upon which it is intended to be hung, and the space all round is filled up by iron wedges; by this means it may be set exactly true in the centre, and also in the plane that is truly perpendicular to the axis. The manner of arranging the wedges is shown in fig. 9, where eight wedges, *b b*, &c. are arranged round the shaft. It is readily seen that the wheel may by means of these be set exactly true, for by fixing a point at the circumferences, and causing it to revolve in its bearings, the inaccuracy of centring is at once detected, and, consequently the wedges at the side, which is in defect of the true or mean circumference, must be driven in, and those on the other withdrawn, until it is found that the circumference at all parts of the revolution is at the same distance from the fixed point. For the purpose of adjusting it in the square, each key way contains two keys opposed to each other, one being driven in on each side of the wheel, so that by gently driving one inwards and the corresponding one outwards, the wheel may be correctly adjusted square, or in the plane at right angles to the shaft, without altering the truth of its centring. Any error may readily be detected by revolving it on its axis, and observing the relation of the plane of the circumference to any fixed point, as in the adjustment for centring.

This is the usual method of hanging wheels, and for large wheels it is the only applicable one; there is, however, a method far superior for such wheels as are not too large and heavy to be turned in a lathe. When this is attainable, the wheel to be turned is made perfectly central on the chuck; and a circular hole, slightly conical, is bored through, into which the shaft or spindle, also accurately turned and slightly conical, is driven. The wheel while in the lathe is also turned true in the sides of the rim and extremities of the teeth, and the pitch-line is also described to mark out the teeth by, so that every thing must be perfectly true with respect to the centre: this, however, is a method only applicable to wheels of small dimensions.

Fly wheels.

(40.) *On the construction of fly wheels.*—As the advantage of fly wheels consists in the momentum generated in their rim, the greatest possible quantity of metal, usually cast iron, is thrown into it and the arms, sometimes made of wood, frequently of cast iron, and in some few instances of malleable iron. Wood is stronger than iron, taking weight for weight; but the attachments are perhaps rather better made with iron, so that commonly the arms are made of the same material as the rim, which, as is said above, is most generally cast iron; and it is only where the velocity is very great that wrought iron is at all recommended, and we are not sure whether it is any where employed. Tredgold says eight feet per second is a good velocity when the arms and rim are both cast iron; that beyond twelve feet the arms ought to be malleable iron, and that thirty-three feet is the greatest velocity that can be allowed, even with a rim of the latter material.

The construction of fly wheels is very similar to that of large spur wheels, being commonly cast in a number of pieces, which are afterwards bolted together; in the

latter, however, accuracy of fitting is the object to be attained, while in the fly wheel strength of construction is of more importance to enable them to resist the tendency to fracture they are liable to from their great velocity. Plate iii. fig. 15 represents a very common mode of constructing fly wheels; the section of the rim is rectangular, and is cast in a greater or less number of pieces, according to the diameter of the wheel; these parts are bolted together by flanches cast on each piece, as shown at *a* in the side figure. The arms are sometimes cast in two parts, and bolted together at the centre, or the centre part or boss is cast in a separate piece, with small arms, terminated by a flanch, to which the arms of the wheel are bolted, as has been already described for large spur wheels. It is usual in fly wheels to secure the boss, when the former method is used, by a malleable iron hoop, pl. iii. fig. 16, which fits in a recess left in the casting, and this being put on hot, by its contraction makes every thing firm and secure. The mode of attaching the arms to the rim is also very similar to that used for spur wheels; a recess is left in the rim of the wheel into which is fitted a flanch, cast upon the arm, and is there secured by rivets or bolts and nuts; rivets are most commonly used in fly wheels to diminish the resistance of the air, which is very considerable at the velocity with which they usually revolve. The pieces *b b* are cast upon the rim to increase the strength at that part, in consequence of the loss of metal by the recess for the arm.

Machinery

Plate iii.
Fig. 15.Plate iii.
Fig. 16.

Sometimes fly wheels are put in motion by a strap passing round their circumference, in which case they are of the shape shown in (fig. 16,) the arms are cast in two pieces with a rim, the section of which is seen in the side figure. These pieces are united at the centre by a wrought-iron hoop, as above described. The pieces *d d*, which form the groove where the strap runs, are bolted or rivetted on each side of the rim, and fit against the flanch *e e*, so as to make a fair surface, and being placed so as to break joint with each other, thus form a very strong and substantial rim.

Fly wheels are sometimes cast with arms and rim, having oval sections, in order to attain as much weight and present as little surface as possible, thereby to diminish the resistance of the air; as this resistance, as well as their friction, is a constant deduction from the motive power of the engine.

Wooden arms, as stated above, are sometimes used in the construction of fly wheels, which gives a wheel more power than one of the same weight in cast iron, as the centre of gyration is thrown at a greater distance from the axis of the wheel. The rim of the wheel under these circumstances is generally put together by a system of dove-tails, which only admit of being fitted in one direction, which is contrary to that in which the centrifugal force acts; these arms are made to fit into sockets in the rim and boss, and every thing is made firm and tight by wedges driven in at the end of the arms in the rim; this method, however, is not often made use of, not being considered so secure as those in which the arms are bolted to the rim.

(41.) *Strength of wheels.*—The strength of wheels, or that of their arms, is a simple case, immediately referable to the article on the strength of materials in our Treatise on MECHANICS. The weight acting on the wheel at the rim is the straining power, the length of the arm the lever, and the part supported by each arm is a fraction of the whole, equal to the number of arms; therefore

Strength.
wheels.

Manufactures. if w = the weight in pounds, r the radius of the wheel in feet, b and d the breadth and depth of the arms in inches, supposing them the same throughout, and n the number of arms; also denoting by a the quantity of allowable deflection; then, according to the article above referred to, or Tredgold's Essay on the strength of cast iron, we have

$$\frac{w r^3}{2656 n a} = b d^3.$$

Consequently, either the breadth or depth being given, the other dimension may be found, or the product $b d^3$ may be found, and each dimension determined. As an example, let us propose a wheel of 6 feet radius, the number of arms 8, the weight acting at its circumference 1600 pounds, and the deflection allowed one-tenth of an inch: then

$$b d^3 = \frac{1600 \times 6^3}{2656 \times 8 \times .1} = 163.$$

Hence, if we make the breadth $2\frac{1}{2}$ inches, then

$$d = \sqrt[3]{\frac{163}{2.5}} = 4.03 \text{ inches the depth.}$$

Frequently, however, the arms are made less deep towards the rim than towards the axle, where the strain is greatest. When this is intended, the number 1640 is to be employed in the denominator, and the result will give the breadth and cube of the depth at the axle. If a wheel be strained till the arms break, the fracture takes place near the axle; it is proper, therefore, to strengthen them about these parts by the metal saved by reducing them near the rim.

Shafts. (42.) *Of shafts.*—These are made of either wood or iron, but at present the latter material, either cast or malleable, is most generally employed. When large wooden shafts are used, they are made either of one large log of oak, or built of fir, with gudgeons inserted into their extremities, in the manner described in a subsequent page. We shall here, however, only speak of those made of cast and malleable iron. Shafts of the larger kind are commonly of cast iron, and their forms are square, solid, cylindrical, or tubular. Wrought-iron shafts and spindles are however generally employed in the smaller Machines, being less liable to fracture than small cast-iron rods, from the blows to which all Machinery is more or less exposed from accidental circumstances. Perhaps large shafts would be for the same reason more commonly made of wrought iron than they are, if it were not for the difficulty of forging them, and the consequent expense attending their use. But whatever may be the material and the shape of the shaft, the journals which revolve in the bearings must be cylindrical, and turned true in a lathe, so that commonly in treating of the strength of shafts having journals, they are the latter only which require to be considered, these being generally less than the shaft, but in other cases we must compute the strength of the shaft itself.

Strength of shafts. (43.) *The strength of shafts.*—This is a question of considerable importance to the practical millwright, but it is one perhaps in which former practice is a better guide than theoretical computation. It has however engaged the attention of scientific men, and Mr. Tredgold in particular has made some valuable deductions; and when his results differ from the usual practice, it is generally on the side of safety.

Machinery. There are different circumstances to be considered in reference to shafts. They have sometimes, as in the case of a water wheel, to support a great weight, independently of the strain thrown upon them by the power and resistance; this will have a tendency to produce deflection, which deflection must be first provided against, and must not exceed $\frac{1}{12}$ th of an inch to 12 feet length. Now if the dimensions requisite to give this transverse stiffness be greater than is required for the twisting power brought on at the circumference, this latter need not be regarded. But in other cases, as in vertical shafts, there is little or nothing of this transverse strain, and the effect of torsion is all that need be considered. Again, in long shafts having a journal, with the power acting at one end, and the resistance at the other; it is not sufficient to provide strength to prevent actual fracture, we must have sufficient dimensions to prevent twisting beyond a certain quantity; and in the latter case it is not so much the shaft itself, which is commonly square, that is to be considered, as the journal, which is necessarily cylindrical, and liable to wear.

As far as regards the strain first alluded to, it has been already treated of under the article *Strength of Materials* in our *Treatise on MECHANICS*. We shall, therefore, only consider that force which has a tendency to destroy the shaft by torsion, here also confining our inquiries entirely to the three following forms, namely, square, solid, cylindrical, and hollow cylindrical shafts, and to the two materials of cast and wrought iron.

It is shown by Mr. Tredgold in his *Treatise on the Strength of Iron*, that if r = radius of a wheel in feet at the circumference of which the power is applied, s the side of a square, or d the diameter of a shaft in inches, t the thickness of metal in a hollow cylinder, and w the weight in pounds, that the following are the equations of condition, viz.

In Cast-iron Shafts.

Square $r w = 150 s^3$
Solid cylindrical . . $r w = 125 d^3$
Hollow cylindrical . $r w = 125 d^3 (1 - p^4)$.

In Wrought-iron Shafts.

Square $r w = 168 s^3$
Solid cylindrical . . $r w = 140 d^3$
Hollow cylindrical . $r w = 140 d^3 (1 - p^4)$.

Where $p = \frac{d - 2t}{d}$.

But, as in practical cases the question is generally the side of the square, or diameter, these are best converted into the following forms:

Cast Iron.

Square $s = \sqrt[3]{\frac{r w}{150}}$
Solid cylinder . . . $d = \sqrt[3]{\frac{r w}{125}}$
Hollow cylinder . . $d = \sqrt[3]{\frac{r w}{125 (1 - p^4)}}$

Wrought Iron.

Square $s = \sqrt[3]{\frac{r w}{168}}$

Manufactures.

Solid cylinder. . . $d = \sqrt[3]{\frac{r w}{140}},$

Hollow cylinder. $d = \sqrt[3]{\frac{r w}{140(1 - p^4)}}.$

These, however, will apply only to very short shafts in which the angle of torsion is small and may be disregarded.

Strength of long shafts.

(44.) When the length exceeds more than one-fourth the radius of the wheel, at the circumference of which the power acts, the twisting effect must be taken into account; and Mr. Tredgold has shown, that in such a case, the shaft being cylindrical, the only necessary form to be attended to, we have

$$d = l^2 \left\{ \left(\frac{r w}{5.2 l^3} + 5184 \right)^{\frac{1}{2}} - 72 \right\}.$$

Or in words, multiply the weight in pounds by the radius of wheel in feet, and divide this product by 5.2 times the cube of the length in feet. To the last quotient add 5148, and from the square root of the sum subtract 72. This remainder multiplied by the square of the length, also in feet, will give the diameter in inches.

Suppose, for example, it were required to find the diameter of a shaft for a water wheel, the length of the shaft from the water wheel to the cog wheel being 6 feet, the radius of the water wheel 9 feet, and the greatest force it will be exposed to 2000 pounds.

Here $\frac{9 \times 2000}{5.2 \times 6^3} = 16$ nearly,
 $\sqrt{16 + 5184} = 72.12$
 Subt. 72
 .12

Then $.12 \times 6^2 = 4.32$ inches diameter.

Generally, however, practical men estimate the resistance, or rather the size of their shafts or journals, by the number of horse-power and the speed of the fly wheel, that is, the resistance is supposed to be as the horse-power directly, and the revolutions inversely; for, with a given power, the velocity will be greater as the resistance is less. And according to this measure Buchanan gives some Tables and Rules, derived from shafts already constructed and of acknowledged good proportions, which he divides into the three following classes: viz. 1st class, steam-engine fly-wheel shafts; 2d class, those in immediate connection with water wheels, or other heavy work; and 3d class, for ordinary internal mill work, and the rule for finding the diameters is as below.

1st class, $d = \sqrt[3]{\left(\frac{h}{n} \times 420\right)},$

2d class, $= \sqrt[3]{\left(\frac{h}{n} \times 200\right)},$

3d class, $d = \sqrt[3]{\left(\frac{h}{n} \times 100\right)},$

where d is the diameter in inches, h the number of horse-power, and n the number of revolutions per minute.

Lateral strain and twisting of shafts.

(45.) We have already stated, that when a wheel is exposed to more than one strain, it will be necessary, and it will be sufficient, to provide against the greater of the two. On this subject, the following remarks of

VOL. VII.

Mr. Tredgold are important; they are given in his edition of Buchanan's Essays on mill work. Machinery.

All shafts are liable to lateral stress and twisting, but it will commonly happen that one of these forces will vastly exceed the other: and, consequently, we need only adapt the shaft to the resistance of the greater power; but, in the first place, we must be able to ascertain when the one or the other must be calculated for.

The resistance of a shaft to a lateral strain must obviously be measured by its stiffness to resist flexure, because it would otherwise play too much on its brasses, couplings, &c., and occasion irregular action in the Machine. From a comparison of shafts in use, it appears that about one-hundredth part of an inch for each foot in length is the quantity of flexure that may be allowed without sensibly affecting the regularity of the motion. In a cast-iron shaft, supposing it to be a solid cylinder, if w be the stress in pounds, when referred to the middle of the length of the shaft, l = the length in feet, and d = diameter in inches, the deflexion in the middle being $\frac{l}{100}$ of an inch, then $\frac{w l^2}{250} = d^4$ or $w = \frac{250 d^4}{l^2}$. (See the Author's Essay on cast iron, Art. 218.)

Now if $\frac{740 h}{v}$ be the twisting power collected at the surface of the shaft, where v is the velocity of that surface in feet per second, and h the greatest number of horse-power that is necessary to work the train of Machinery to which the shaft belongs, we have

$$124.8 d^2 = \frac{740 h}{6 v};$$

but the velocity of the surface of the shaft is equal to its circumference in feet, multiplied by the number of revolutions in a second. And if this number of revolutions

be n , then $v = \frac{11 n d}{42}$; and the equation between the

stress and strain reduces to $d^3 = \frac{3.78 h}{n}$. It therefore

appears, that when $\left(\frac{3.78 h}{n}\right)^{\frac{1}{3}} = \left(\frac{w l^2}{250}\right)^{\frac{1}{4}}$ the strain from torsion will be equal to that from lateral pressure,

whence if $\frac{1472}{l^2} \times \left(\frac{h}{n}\right)^{\frac{4}{3}}$ be less than w , the diameter

of the shaft must be determined by the rule for lateral stress, and if it be greater than w calculate the diameter by the rule for torsion. For the advantage of those who are not much versed in calculation, it may be of use to remark, that in common cases when the stress in pounds, multiplied by the square of the length in feet, is less than 3000, the twisting strain will be greater, and the contrary.

In a series of lying shafts, it is necessary to make the journals equal to the twisting, with the addition of the necessary allowance for wear, and it will, therefore, often be necessary to adjust the shaft to both strains. But in all instances where the lateral strength is less

than $\frac{1472}{l^2} \times \left(\frac{h}{n}\right)^{\frac{4}{3}}$ the bodies of the shafts need not be greater than the journals

Manufac-
tures.
Couplings.

Coupling-
box.

Couplings
for two
bearings.

Plate ii.
Fig. 1.

By Mr.
Murray.
Fig. 2.

(46.) *Of Couplings.*—The conveyance of motion by the connection of shafts would be a matter of great simplicity, if it were possible to construct Machinery mathematically true, and if their supports were not liable to settlement, and their parts secure from wear and tear. But in practice, it is found from these causes to involve some difficulty, and, accordingly, a number of different methods have been proposed.

Of these the most simple is to make the ends of the shafts square, and to employ what is called a square coupling-box, of exactly the same interior dimensions as the ends of the shafts into which the latter are fitted, so that when one shaft is put in motion the box connects them in such a manner that the two must revolve together; but when occasion requires it, the box may be slipped back upon one shaft, and the other disengaged or removed, either for the purpose of discontinuing the motion or for repair.

If the axles of shafts could be brought practically into a straight line, and the square ends made and fitted to the box with perfect accuracy, the motion would evidently be smooth and continuous, but in large Machinery this is impossible; and even if it were possible this perfection would not continue long, in consequence of the wearing of different parts, and the unavoidable settlements that too commonly occur. As soon as either of these happen the shaft is in some part of its revolution lifted off the bearings, thus producing an unsteady motion, with considerable straining and wearing of the couplings, by which they in their turn suffer and produce a further evil.

For these reasons the square coupling-box has been a good deal abandoned in mill work, although it is still used in smaller Machines, where it can be executed with greater accuracy, and is not liable to the same evils as in larger works. However, even in small Machines, the square coupling has been in many cases supplanted by the cylindrical box, in which two pins at right angles to each other are inserted through the box and shaft to connect them together. Here there is no wear, except in the holes and pins, which latter can be easily replaced, and greater accuracy in the fitting may be attained, because both the shaft and the box may be turned in a lathe, and thus fitted to each other with the utmost precision.

(47) It is proper to observe also that couplings in general are more easily applied when each shaft has two bearings, but sometimes one of the shafts has but one, and in these cases the boxes above described are very commonly employed, at others a scarfed joint is used, and the parts bolted together. Various other means are likewise adopted in different Machines, which will, however, be more appropriately given in the explanation we shall have to offer of them individually.

When a shaft has two bearings, a very usual mode of coupling is represented in plate ii. fig. 1. Here the shafts are terminated with circular heads, one having teeth and the other corresponding indentations to receive them, and thus one is made to give motion to the other; while if any slight settlement of the building, or other cause, depress one of the bearings, or raise another, so as to put the two shafts out of the perfect straight line they ought always to preserve, these joints will admit the slight flexure and still communicate steadily the motion of the one shaft to the other.

In fig. 2 and 3 is represented a coupling-box first used by Mr. Murray, of Leeds, for connecting a long line of

shafts which have to carry a heavy strain. It is so formed that it communicates the motion in the manner of an universal joint, should the shafts be out of line. Let A and B be the two shafts to be united; C D their necks, or collars, which lie in the bearings; the ends projecting beyond these have boxes, E F, fixed on them either by a square with wedges, or by a round part with a fillet; one of these boxes, E, has a piece projecting from the inside of it on each side, and extending into the other box, as is shown at *a a*, (fig. 3,) which is an inside view. The box F has two similar pieces projecting from it at *b b* into the other box E; within the boxes an iron cross, *c c, d d*, is situated, it has screws fixed into the end of the arms, and by these the motion is communicated: thus the pieces *a a*, when the shaft A and box E are turned round in the direction of the arrows, act against the screws *c c* of the cross, and cause them to revolve, at the same time the other two screws *d d*, at the other arms of the cross, press against the pieces *b b*, which belong to the box F and shaft B, thus putting them also in rotation. The cross is placed quite detached in the boxes, and thus acts as a universal joint to communicate the motion of one to the other; the screws *c c, d d*, at the end of the cross, are only made use of in order that the acting points may be of steel, which may be made smooth, so as to have but little friction.

Another mode of uniting shafts, by Mr. Murray, is shown in fig. 4; this has the advantage of requiring only one bearing for every length of shaft, whereas that above described requires one at each end of every length. A and B represent the two shafts, each having a pivot formed at the end; these pivots are fitted into a coupling piece C D E, which is bored inside to receive the ends of the shaft, and turned outside with a neck D D, which works in a bearing; the two shafts, A B, are connected with the coupling piece D, at C and E, by means of a cross key *l m* put through each shaft, and the ends of them are received in notches made inside the coupling piece at C and E, where it receives the end of the shafts. It is to be observed, that the shafts do not fit tight in these pieces E and C, but only in the pivots *a b*, by which means they have a little freedom of motion, and this without straining the bearing in which D runs, because it is only the short coupling piece which is received therein; and, consequently, a slight deviation from the straight line will have no tendency to produce any injurious strain.

(48.) *The universal joint*, called also *Hooke's joint*, from the name of its inventor, Dr. Hooke, furnishes another method of uniting shafts which are inclined to each other. This contrivance is shown in fig. 5, where A and B are two shafts, the ends of which, within the bearings C and D, are formed in the shape of a fork. G is a circular iron ring, with four pins or pivots, *a a a a*, on its circumference, which fit into holes in the ends of the forks, by that means uniting them together, and at the same time allowing freedom of motion. In this way rotary motion may be conveyed from one shaft to another when they have considerable inclination; still, however, if the angle of the shafts be more than 15 degrees, it is advisable to use bevelled wheels, as when so much inclined, the universal joint works with great friction and irregularity of motion.

(49.) Fig. 6 is a method of coupling shafts, called the friction coupling, where the connection depends simply upon the contact of surfaces. It cannot, perhaps, be so well applied to heavy Machinery, but there are a variety of

Machinery.

Coupling
by a uni-
versal joint.

Fig. 5.

Friction
couplings.

Manufactures. circumstances where it can be used with more advantage than any other method. One of the shafts, A, has a circular plate cast upon the end of it, which fits into a loose box upon the end of the other shaft B; *b b* is a collar of leathers which fits within the enlarged end of the shaft B, so that when the nuts *a a* are screwed up, it causes the box D to press against the collar of leathers, and by its friction puts the shaft B in motion. A collar of leathers is also sometimes placed at the end of the shaft, as shown at *c*. This method is highly to be recommended in a variety of Machinery, particularly in turning and boring Machines, where it can be screwed so as just to have sufficient friction to carry on the work with its ordinary resistance; but so little beyond it, that should any accident happen, such as a tool getting foul, or any thing getting entangled with the Machinery, the additional resistance will stop it, the other part continuing its rotation, and by that means often preventing not only damage to the work under operation, but injury to the workmen themselves.

In the above description of coupling shafts together, we have confined ourselves principally to those which are intended to be permanent; other methods are employed in cases where it is necessary to engage and disengage Machinery in the course of its operations; these are described below.

Methods of engaging and disengaging Machinery. (50.) *Of the Engagement and Disengagement of Machinery.*—In the numerous contrivances for this purpose the particular object aimed at has been to communicate motion without a shock; as in consequence of the inertia of bodies, or their disposition to remain in the state in which they are, the parts of Machinery when acted upon too suddenly by a moving power, are liable to fracture and disarrangement. The inventions for this purpose may be divided into two classes, *viz.* when the motion is communicated by bands, belts, or chains, and when it is communicated by wheel work; the former generally possesses the advantage of bringing on the motion more gradually, although the application to large Machinery is attended with inconvenience.

by fast and loose pulley, Fig. 7 represents a contrivance, termed the fast and loose pulley, which is remarkable for its simplicity. It is attended with no shock, and is considered the most perfect method yet invented for the purpose where it can be applied. It consists simply of two pulleys, B and C, one being fixed on the axle, and the other loose, and the belt or band which conveys the motion may be shifted at pleasure, either upon one pulley or the other; by that means putting in or out of motion the axle A. It may be proper here to mention, that in order to make a belt run properly on a pulley, it is necessary to have the rim a little rounded or swelled in the middle. The belt always inclines to that part of the pulley which is of greatest diameter. This curious property is of great practical use, and until it was known, it was found very troublesome to prevent belts slipping off the pulleys.

by a gland, Fig. 8. Another very common contrivance for disengaging and re-engaging a Machine moved by a belt or band is shown in fig. 8, where the pulley P revolves upon a shaft A B, to which it is occasionally required to be connected, in order to convey motion to the Machinery. To effect this, the axle has a cross piece or gland, D E, firmly attached to it, and upon the wheel, which is made free to slide upon the shaft, one or more projecting pieces or teeth are cast, so that when, by means of the handle F G, the wheel is moved towards the gland, the projecting teeth engage the limbs of the gland, thereby

carrying it round, and with it of course the axle A B, to which is attached the Machine intended to be put in motion. This contrivance is however attended with a shock which renders it very inferior to the last mentioned. There are besides these a great number of other methods used by different masters when motion is conveyed by straps; but as they consist of a variety of forms of the same principle, it is not necessary to enter into a further description of them. Let us, therefore, next endeavour to describe some of the methods made use of when motion is conveyed by wheelwork.

(51.) When a mill is in motion, we may with perfect safety throw wheels out of gear; but in throwing them in gear, there is great danger of breaking the teeth, particularly at high velocities, so that such a method of disengaging and re-engaging when motion is conveyed by wheelwork can only be employed in such Machines as rolling mills, and a few others, where the velocity required is very slow.

A method which is more commonly used, and is more applicable to the generality of Machinery, is shown in fig. 9, where A B represents a shaft to which is attached the Machinery required occasionally to be put out and in motion, and C C a wheel which is made to revolve freely upon it by means of a bush, and which is always in motion from the millwork. The part of the shaft marked A is square, and the clutch D D is made to slide freely upon it by means of the handles E F, so that it may be readily put in motion by engaging it with the revolving wheel C C. In this method, also, a considerable shock is given to the Machinery when the connection is made; but there is no liability of fracture, as the teeth of the clutch may be made of any thickness.

A mode of disengaging and re-engaging, termed the *locking bayonet*, is sometimes preferred. The construction is as follows: strong arms, A A, fig. 10, are fixed fast on the shaft R just before the wheel, either by a circular fitting with a fillet by a square, or they may be cast upon it; through the extremities of these arms holes are drilled to receive the shanks, *ff*, of the locking bayonet, which are fixed fast by nuts to an arm D D, very nearly similar to A A, but it slides upon the shaft, and has a central part, *g*, with a circular groove round it, in the manner of a pulley. A fork, embracing the central piece in the groove, gives the means of sliding the bayonets *ff* and D upon the shaft, so that the points of its shanks intercept the arms of the wheel, and carry it round with them and the shaft; but when the points of *ff* are drawn back clear of the arms of the wheel, it revolves freely without turning the shaft.

In consequence of the defects attending this as well as the former mode of connection, that is, the injury done to the Machinery, several other attempts have been made to invent one where the motion may be brought on more gradually; and have indeed been attended with considerable success in the method termed the *friction clutch*, which is shown in fig. 11. Here A B is the part of a shaft kept in motion by the mill; C D E a bayonet, which either slips on a square part of the shaft A B, or passes through the arms of a cross H I, (as represented in the figure,) which cross is fastened to A B. F G is part of the shaft to be connected with A B; upon F G a kind of drum or pulley is fastened, with a hook, L M on the outside, which by means of screws at *a a* is made to press gently upon the surface of the drum. In setting the Machine in motion, the hoop L M is carried round by the bayonet or clutch C D E, and by

Manufac-
tures.

the friction of the hoop upon the drum brings it into motion in the same easy and gradual manner that a belt does a Machine which is driven by a pulley; but the hoop is found to answer better when it is made to act as a spring upon the drum. There is a great deal of ingenuity in this contrivance, it may be applied to large Machinery, and variously modified according to circumstances, and it is obvious also that it prevents the shock or strain upon the Machinery which is the objection to the other methods. It may likewise prevent injury to the mill itself, arising from belts getting foul, or from chips, &c. falling in among the teeth of wheel-work; for in most cases of this kind the hoops would slip upon the drum and allow that part of the Machinery to stop without sensibly altering the general motion of the mill, while with the common method the whole motive force of the mill would continue to be exerted, and would probably fracture or strain some part of the Machinery before the accident might be discovered.

Gudgeons.

(52.) *Gudgeons*.—It is always desirable that gudgeons should be formed of the same piece as the shaft, because the slightest deviation from the straight line causes them to strain and work very irregularly in their bearing. In wooden shafts this is, of course, impossible, and is one of the chief objections to their use. When it is considered that the direction of the stress which tends to loosen a gudgeon in a wooden shaft is continually changing, and that such action is exerted upon wood, a material that is so very easily and permanently compressed, it will not be wonderful that it should have been found difficult to render them firm and lasting; and before the improvement called the cross-tailed gudgeon, the prevention of their becoming loose in the shafts was attended with great trouble and expense.

Cross-tailed
gudgeon.
Plate iii.
Fig. 1, 2.

A cross-tailed gudgeon is represented in plate iii. fig. 1 and 2, which is made of cast iron, and turned true; it has four leaves, *a b c d*, forming a cross, which are let into the end of the wooden shaft *A*; the front edge of each leaf is considerably thinner than the back, so that a pair of strong iron hoops, *h h*, being driven tight upon the end of the shaft, closes the wood round the cross and holds it fast; the back of the leaves being also wider than the front, it will not come out. As an additional security, screws are sometimes put in through holes in the arms of the cross, which are in that case made thicker, and do not go so far into the wood. The screws go into the timber a considerable distance, where a mortise is cut into the wood to meet the end of the bolt, and an iron nut is dropped in which is screwed upon the end of the bolt by means of a spanner. By this contrivance, a gudgeon may be fitted into a wooden shaft very fast, but still it will never come into competition with iron shafts where the gudgeon is made in one solid piece with the shaft itself.

Another
form of
gudgeon.

Fig. 3, 4, 5.

An improved method of fixing gudgeons is described in the *Transactions of the Society of Arts*, vol. xxxi. p. 223; it consists in casting the gudgeon with cross arms, which fit into proper notches in an octangular box of cast iron, which has been previously fixed on the end of the shaft. *A A* (fig. 3, 4, 5) represents a portion of the end of the wooden shaft, which is of an octangular form, and has the water wheel fixed upon it; it is long enough to reach across the pit in which the wheel works, and having a gudgeon at each end, is supported and revolves upon them in proper bearings.

B B is the cast-iron box fitted fast upon the end of the shaft, and being wedged tight prevents the wood from splitting as effectually as any hoops can do; upon the end of the box is a projecting flanch *a a*, and in the face of this, four grooves or notches are made for the reception of the arms of the iron cross *b b, d d*, which is part of the gudgeon *c*, on which the shaft revolves; this cross is firmly attached to the box by four screw bolts, which pass through the flanch, and also through the ends of the arms of the cross, having nuts screwed on the outside to make all fast. The section (fig. 5) shows the cross piece and box separated to explain the manner of fitting them together, the inside face of the cross having projections *e e*, which enter the end of the box, and keep the pivot in its true centre; thus the bolts have only to hold the gudgeons fast on the end of the box, the principal strain being taken off by this manner of fitting the cross into the box. When the gudgeon of a wheel fitted on this plan becomes worn out so as to require replacement, it can be removed by taking off the four nuts, and a new one applied; the gudgeon also being of small dimensions, it will admit of its cylindrical part being very conveniently turned in a lathe, which is a considerable advantage.

In vertical shafts, where their own weight, as well as that of the Machinery attached to them, is supported by their lower extremity, this method is greatly preferable to the cross-tailed gudgeon, as it affords support to a greater surface of wood. For lying or horizontal shafts, there is no method, at present introduced, preferable to the cross-tailed gudgeon.

(53.) When an iron shaft is cast solid, the gudgeon is formed in the same piece with it, differing from the other part only, in being generally smaller, and turned truly circular, in a lathe. The necessary strength of gudgeons will be considered in a subsequent page, although in most cases, in practice, they are made larger than their strength requires, as the wear and tear of small ones, as well as the brasses in which they revolve, is very great. In vertical cast-iron shafts, the pivot is usually cast somewhat in an egg shape, being rather smaller at *a*, (fig. 6.) to prevent it from binding in the step; another mode is, to terminate the shaft flat at the lower end, having a small oblong recess in it. To this end is fitted a round piece of steel, *A*, fig. 7; flat below, except having a groove, *a*, across it, similar to that in the head of a screw, the use of which is to feed it regularly with oil. A pivot or step, on this construction, was presented to the Society for the Improvement of Arts, and was said to have been twenty years in use, in a horse mill, without being perceptibly worn. It has been since applied in the case of heavy upright shafts, where other means were found inadequate to prevent the action of the pivot, and has given great satisfaction in its use. It is to be observed, however, that it does not answer so well in cases where there is much lateral pressure, and a better mode is now in use in several mills. This consists in having the steel pivot made cylindrical, and fitted into the foot of the upright shaft. The bottom of the step is made convex, and there is interposed one or more pieces of steel, formed like a double convex lens: these pieces of steel, having a little motion, make the relative motion of the pivot less, and consequently diminish the friction. We may also add, as an entirely different method, that Mr. Bramah, in the specification of his patent for Machinery for surface planing, includes a mode of running pivots entirely on a fluid, and raising and depressing

Machinery.

Fig. 5.

tures.

them at pleasure, by means of a small forcing pump and stop cock. This method, however, has not been brought into general use, but is practised, in some cases, as in the Planing machine in the Royal Arsenal, Woolwich.

Gudgeon
for hollow
iron shafts.

Fig. 8, 9.

(54.) The best shape to give strength to cast-iron shafts, is tubular or hollow cylindrical, in which, of course, it becomes necessary to make the gudgeon in a separate piece, which is some inconvenience. This, however, can be attached to them in a much firmer manner than in wooden shafts, and if executed in a good workman-like way, will last for a great length of time, without any deviation from truth. A B (fig. 8 and 9) is a section of a cylindrical shaft, at each extremity of which the metal is left thicker for some distance, and three ribs, *a, a, a*, cast upon it, having key ways left in the face of them; *cc* is the gudgeon, which has three arms or feathers, cast or wrought upon it; having also key ways left in their faces, which correspond with those on the ribs, in the end of the shaft. A wrought-iron hoop, *h*, is then put on the end of the shaft, to prevent it from splitting, and the gudgeon being adjusted in its place, is driven tight by keys or wedges. The gudgeons are sometimes made with four arms, but it is not considered good, because, in driving the keys, it is difficult to make them all bear alike; whereas, they necessarily must bear alike with three arms; for in driving one key, the other two must be tightened also. In the smaller hollow shafts, the gudgeons are usually made without arms, being a solid cylinder, having key ways cut in three places on its surface; this fits loosely into the end of the shaft, and is made tight by keys, as in the other method. Gudgeons are sometimes turned after they are secured in the shafts; but, in ordinary cases, sufficient accuracy is obtained by turning them before they are attached, which is most convenient, and then adjusting them, by the keys, centrally with the shaft.

Fig. 10.

A mode of securing gudgeons, best suited to vertical cast-iron shafts, is represented in fig. 10; where A B C D is part of the end of a shaft, which is bored out truly circular, and the gudgeon turned true, to fit it; a circular flanch is cast round the extremity of the shaft, which sets against a similar one in the gudgeon, and is secured to it by screw bolts and nuts, as seen at *a a*, in the figure. This method involves a great deal of workmanship, and is consequently more expensive than the one described above. The pivot is sometimes made of steel or wrought iron, and being turned slightly conical, is fitted into the gudgeon, as shown by the dotted lines in figure 9; so that in circumstances where pivots are liable to a great deal of wear from grit, &c., as in the case of the gudgeons of water wheels, they may, at any time, be easily replaced.

(55.) *Strength of Gudgeons* — Gudgeons having all the weight of their shaft, wheels, &c. to support, ought to be made sufficiently strong for that purpose; while to avoid unnecessary friction, their diameter should be as small as possible, consistently with the liability to wear, and convenience of workmanship.

The strength of a gudgeon is limited by the strain Machinery. it will bear, without permanent derangement of its structure, as the length is always so small with respect Strength of to the diameter, that the flexure will be, in all practical gudgeons, cases, insensible; and the calculated stress should include every kind of force acting on the axle or shaft; the diameter should also be determined, so that the gudgeon may be capable of resisting the whole, if it were thrown on the extreme point of its bearing.

If *w* be made to represent the utmost amount of the stress in hundred-weights, and *l* the length of the gudgeon, in inches, from the shoulder to the extreme point of bearing; it is shown (Tredgold's *Essay on Cast Iron*, Art.

138) that $\frac{(112 w \times \frac{1}{12} l)^{\frac{1}{3}}}{5}$ or $0.42 (w l)^{\frac{1}{3}} = d$, the

diameter of the gudgeon in inches. But an allowance should be made for wear, which will be nearly directly as the stress, and inversely as the length of the bearings; consequently, the length of the gudgeon should be greater, in the same ratio, as the stress is greater. And until some more certain principles be found of proportioning the gudgeons of a Machine to the nature of its service, we may allow one-fifth of the diameter as a provision against wear, when no gritty substance is likely to affect them; and one-third in all cases where they are exposed to gritty matters. In the former case, the rule will become $\frac{1}{5} \sqrt[3]{w l} = d$, or $0.5 (w l)^{\frac{1}{3}} = d$; that is, multiply the stress in hundred-weights by the length of the gudgeon in inches, and the cube root of the product being multiplied by 0.5 will give the diameter of the gudgeon in inches; and in the latter, when the gudgeon is likely to wear much, from the nature of the Machine, or its particular situation, multiply the cube root of the product by 0.56, instead of 0.5.

Buchanan, however, states, that it is found, from observation, that in actual practical cases, the cube root of the weight in hundred-weights gives very nearly the diameter of the gudgeon in inches, which is a very simple rule.

(56.) The following Table is a statement of the proportions of the gudgeons of several water wheels, in actual service and which have been found to give satisfaction in their working. The 1st column contains merely the ordinal numbers. 2d shows the material of which the wheel is made. 3d the diameter in feet. 4th the width in feet. 5th the description of wheel. 6th the diameter of the gudgeon in inches. 7th the weight of wheel in tons and hundred-weights. 8th the diameter in inches, derived from Mr. Tredgold's rule, for the case of greatest wear; the length of the gudgeon being assumed equal to the diameter, which is the usual proportion in practice. 9th is the same, calculated for the ease of ordinary wear. 10th is the diameter of the gudgeon in inches, derived from the practical rule mentioned above, being the cube root of column 7, in hundred-weights.

The water wheels in the Table were all in the middle of their respective shafts; both gudgeons of each wheel had therefore equal stress.

Remarks on the Table.

(57.) It will be observed by examining the numbers in the above Table, which are all cases of water wheels, that the diameter of gudgeons, computed according to the preceding rule for extraordinary wear, exceeds the diameter determined by taking the cube root of the weight in hundred-weights, and also those in actual service, at least with only one or two exceptions; but for the case of less wear the diameters are smaller, the cube root of the weight in hundred-weights forming a sort of mean between the two, and as the stress, wear, &c. of water-wheel gudgeons are not exposed to such evils, as to consider them of the first class, although perhaps they may exceed the other, the simple practical rule given by Buchanan may be considered well adapted to that particular nature of service.

In the above investigation our attention has been confined to the case of cast-iron gudgeons, which are generally preferred in consequence of their being cheaper and more conveniently formed than wrought-iron ones. Still, however, there are many cases in which wrought-iron gudgeons are employed, and considered preferable. In these, of course, the diameters may be made smaller than in the preceding Table. The relative resistance of wrought and cast iron are to each other as 14 to 9 where the permanent change is considered; and as the resistance to this change is also as the cubes of the diameters, it follows, that where the same resistance is required, the diameters in the two cases may be made inversely as the cube roots of these numbers, or as $\sqrt[3]{9} : \sqrt[3]{14}$, or as .87 to 1. Therefore to find the diameter of a wrought-iron gudgeon we have only to find first that of a cast-iron gudgeon, and multiply that diameter by .87.

Plumber blocks and steps.

(58.) *Plumber blocks and steps*, as we have before defined, are those parts of Machinery which support the pillows, or bearing upon which the pivots and gudgeons of shafts immediately revolve. The pillows, or as they are improperly termed by millwrights *brasses*, are usually made of a composition of copper and tin, very much resembling gun metal, which is much harder and much more durable than common brass, and is found to work with wrought and cast iron with very little friction. (See Art. 20.) Other substances which are cheaper are occasionally made use of, and have in many instances been found equal, at least in durability. At the cotton works of Deanston, near Down, a water wheel has been run-

ning nearly thirty years on pillows of cast iron, with little sensible wear on the gudgeons; nor were they ever liable to heat, which is a good test of the absence of friction. The outer surface of cast iron, particularly when cast in a metallic mould, is remarkably hard, which renders it very durable, at the same time if it be polished to a good surface it will work with little friction. Such pillows, it has been said, are best applied to wrought-iron gudgeons or pivots, but this seems at variance with Mr. Rennie's experiments. (Art. 19.)

Wooden pillows are sometimes employed. Box tree and lignum vitæ were long in use; the latter has however been found an improper substance for the purpose; beech is preferable to either, and has been used with great success for steps, for which purpose also holly has been found to answer very well.

Fig. 11 is a representation of a plumber block, showing the manner in which the pillows are fixed in their supports. *aa* is a cast-iron plate, which is secured by two or more bolts, *bb*, down to the timber or framing of the mill; upon this plate are cast two pillars or supports, *cc*, between which a piece of brass, *l*, is bedded, and has a semicircular notch in it, in which the gudgeon or pivot of the shaft revolves. Another similar piece of brass is fixed into the cast-iron cap piece, *dd*, which is fitted into the space between the two pieces *cc*, and is drawn down firmly upon the gudgeon by the nuts upon the two bolts *ee*. The brasses are prevented from getting out sideways by small fillets projecting from the middle of them, which are received into proper grooves in the cast-iron work. In the same way the cap *dd* is fitted between the pieces *cc* with a fillet and groove, so that it cannot deviate sideways, and then the bolts have only to draw the brasses together. Sometimes a bearing of this kind is fitted up so as to be capable of adjustment, in which case an iron plate, *ff*, is bolted down to the framing, and the bearing plate, *aa*, lays upon it, the same bolts, *bb*, passing through both, and also through the framing beneath. The holes through which they pass in the piece *aa* are oblong, to admit the whole plumber block to be moved sideways, which is done by two wedges *gg*, so inserted at the end of the plate *aa*, between it and the pieces *mn*, which are cast upon the lower plate for the purpose, and can by this means be accurately adjusted in a horizontal direction. The plate *aa* can be raised or depressed by

Pl. iii.
Fig. 11.

Manufac-
tures.

the wedges *h h*, upon which it rests, so that by these means the axle may be adjusted in the exact position required, and then all screwed fast by the bolts *b b*.

The best way to make the interior surface of the brasses for a bearing exactly true, is to have them cast solid, that is, the two halves of the brass in one, with a notch which very nearly but not quite separates them. In this state they can be chucked in a lathe, and the inside bored or turned out true; they may then be separated in two halves, and put into their places to which they should have been previously fitted. Sometimes the bearing is all fitted together, and screwed down in its place, and a borer is made use of to bore or broach out the hole for the brasses.

Friction
rollers and
wheels.

(59.) *Friction rollers* are sometimes employed to diminish the quantity of friction in a bearing: but not with much advantage in heavy Machines, because they are liable to get out of order and require very accurate workmanship. Their effect depends upon converting a sliding into a rolling motion, with only the friction or sliding of the small axis which retains the roller in its place. Friction wheels are also used for the same purpose: they differ from the rollers in this, that the stress is born by the axles of the friction wheels, and by the surfaces of the rollers. The manner of constructing friction wheels is shown in fig. 12 and 13: *a a* is an iron plate which is bolted down upon the framing; it has holes in it to receive the friction wheels *b b*, and has supports cast upon it which are provided with sockets for brasses, in which the pivots of the friction wheels revolve. The friction wheels being fixed in their places, the gudgeon *c* of the shaft lies between them, so that when it turns round it rolls upon them, or rather their circumferences move with it, and, consequently, the pivots of the friction wheels move so slowly as to diminish the friction materially, the proportion depending upon the relation between the diameter of the wheels and the gudgeon.

Fig. 12, 13.

These are, however, much inferior to the friction rollers, if the latter are executed with any degree of accuracy. Plate. iii. fig. 14, is a representation of a set of friction rollers. Here *a a* is an iron plate bolted down to the framing, upon which are cast circular rings *b b*, the interior surface of the ring is turned in a lathe with the greatest accuracy, and the pivot or gudgeon *e*, which is also turned true, rests in its centre, being supported by six rollers, *c c c*, &c. arranged at equal distances of such diameter as to exactly fill up the space all round between the gudgeon and the ring. The rollers, it is evident, must be made all of one exact diameter, and extremely true, and must also completely fill up the space. The gudgeon in revolving has a tendency to turn these rollers, but as they have no fixed centre, they will roll round within the ring in the same direction as the motion of the gudgeon, but very slowly, their velocity being in proportion to the diameters of the gudgeon and the ring *b*. In order to keep the rollers at their relative distances from each other, each one has a groove turned in the middle of its length, as shown in the side figure at *h*, and an iron ring *l*, having six holes or notches in its outer circumference at proper distances for the centre of the rollers, is made to fit upon them. They will, by this means, be kept at their proper distances asunder, and when the gudgeon *c* is introduced between them they will take their proper places and lie truly parallel. It is to be observed, that the notches or holes in the ring *l* do not exactly fit the neck of the

rollers, which have, therefore, considerable play and but little friction; for it is not essential in order to keep the rollers at their relative distances that this ring should be used, except to prevent the danger of their getting displaced by some accident. To prevent dust or dirt getting in, which greatly destroys the action of the rollers, a circular iron plate is fitted into the ring *b* on each side, and secured to it by small screws. One of the circular plates must of course have a hole to admit the gudgeon. These plates are, also, useful in preventing the rollers from shifting their position endways; but to prevent friction, if ever they come in contact, the ends of the rollers should be made a little convex, as shown at *h*, that they may touch at the centre rather than the outsides; they will, however, never bear hard against the plate, having no tendency that way.

Machinery

(60.) A patent was taken out for these friction rollers many years ago, and a large Manufactory was established for making them for various purposes, as carriage and waggon wheels, the gudgeons of water wheels, &c. They were found to possess great advantages, having scarcely any sensible friction when in motion, but were very liable to get out of order, chiefly from the entrance of dust, which occasioned the rollers to wear out of the round more on one side than the other, from inequalities in their hardness, and if once, by any means, the rollers stood still for an instant, the gudgeon wore a flat place in the two rollers beneath it, and they would never run round again; of course, when this effect took place they soon became loose, and presented a greater degree of resistance to the gudgeon than the common brasses. For delicate purposes, where hardened steel can be employed for the rollers and ring, they are still used with advantage, but for ordinary Machinery, the imperfections above described have caused the use of them in most cases to be abandoned.

Patent friction rollers.

For the bearings or steps of vertical shafts, steel is more commonly made use of, as from the great weight they have to support the wear of brasses is very considerable, and requires them to be often replaced, which is generally attended with inconvenience.

(61.) Conical friction rollers are sometimes applied to vertical shafts to diminish the friction. Plate ii. fig. 12 represents a set of rollers for this purpose. *A A* is a plate which supports the weight of the shaft; it has a conical part cast upon it with a hole in its centre, into which is fitted the pivot *B* at the bottom of the shaft. The shaft *D* has a conical plate attached to its lower extremity exactly similar to the conical ridge upon the plate *A A*, and between these two surfaces the friction rollers are situated, which of course bear the whole weight of the shaft, and whatever Machinery is attached to it; the pivot being required simply to keep the shaft in its place. The collars are kept at proper distances asunder by a ring shown separately at *l*, fig. 13. It has three projecting arms, which, being formed into spindles, pass through the centre of the rollers, and the latter secured in their places by collets and cross keys. Now it will be readily seen, that as the shaft revolves the rollers will turn upon the plate *A A*, and thus render the friction much less than in the ordinary kind of bearing. These have, however, the same defects as those attending the friction roller for horizontal shafts already explained, that is, they require exceedingly accurate execution at first, and they have the same tendency to wear out of adjustment, from the entrance of dust, dirt, or other substances and causes not in the power of the

Conical
friction
rollers.
Pl. ii.
Fig. 12.

Fig. 13.

Manufac-
tures.

Framing
mill work.

mechanic to control, so that they are by no means in general use.

(62.) *Framing of mill work* is so varied in its construction, according to the nature and situation of the Machinery it has to support, that a detailed description will be better entered into when necessary under the head of each Machine, and we shall therefore here only speak of the general principles of construction, and describe such parts as are common to all Machinery.

Mill work from its motion occasions a tremour on all parts of its framing which renders it liable to become loose in the joints, and subjects it to a much more speedy derangement than common carpentry. It is besides subjected to violent sudden thrusts from the bad action of wheels, or from reciprocating motions. Wooden framing therefore ought to be made much more strong and stiff than the mere support of the weight would demand, and at the same time sufficiently heavy to give solidity and steadiness; for where the framing of Machinery is not firm and well bound, and a vibratory motion takes place in its parts, such motion expends a considerable portion of the power employed. This loss of power is very difficult of investigation: it is certain, however, that whatever motion of a vibratory nature is communicated by a Machine to the framing and objects in contact with it, must be lost to the effect it would produce were it totally free from such motion. It is to be observed, that light framing made firm and well braced, is preferable to that which is more heavy and not so well connected in its parts; in fact, that stiffness is rather the object to be aimed at than weight, as the heavy framing in its vibration will expend more original power.

Besides strength, stiffness, and solidity, the framing of mill work requires to be constructed so as to be easy of repair, and so contrived that any particular part may be repaired or renewed with the least possible derangement to the other parts of the framing. There is also another consideration which should be attended to, namely, that shafts by the wearing of the gudgeons and the brasses in which they revolve, get out of their true situation, to remedy which the part of the framing which supports them ought to be so constructed as to admit of adjustment. When the motion of the shaft is communicated by the action of toothed wheels a little settling of the shaft from wear, or warping of the framework by putting the wheel more shallow or full in gear, materially affects the action of the Machinery, and in such cases the adjustment of the bearing is a matter of particular consideration. It is found of advantage that the part on which the axle rests should have a small degree of elastic tremour when the Machine is in motion, as such tremour has considerable power in diminishing the friction. It may further be observed, that framing to support Machinery should be as independent of the building as possible, because the tremours it always communicates is exceedingly injurious.

Cast iron possesses great superiority over timber in the construction of framework. It is not only much more durable, but by possessing the advantage of being of uniform texture, and of being cast into any shape, its strength may be beautifully arranged to support the particular kind of stress it has to bear. Timber, on the other hand, being stronger in some directions than in others, and of very limited breadth, is confined in its arrangement, and requires in certain cases much workmanship. See Buchanan on Mill Work.

(63.) *Equalization, Transmission, and Conversion of Motion.*—Although we have hitherto only described the detached part of mill work, and have not at present been able to do much more than give a simple definition of the term Machine, it is necessary to assume that the reader has a more general idea both of the nature and object of a Machine and of Machinery generally when in action, than can be included in a mere definition. It is impossible to carry forward a Treatise on such a subject as the present, with the same precision and order as a Treatise on Geometry, where we proceed from definitions to axioms, from these to theorems, problems, &c., never allowing the employment of a term that has not been already illustrated in some preceding part. In Machinery this cannot be, it is impossible to define and illustrate some of the elementary parts, without a reference to the whole of which that part is only a member, and this must be the case in the present instance in which we are about to speak of Machinery when in motion.

On Equalization of Motion.—The regulators most commonly had recourse to for the equalization of motion may be reduced to the four following: the pendulum, the fly, the fly wheel, and governor, to which, indeed, we may add the air pump.

(64.) *Of the pendulum.*—This regulator is only employed in Machines, where the primary object to be obtained is a uniformity of motion, and its principal use is therefore confined to clocks, or in the form of a spring pendulum to watches and chronometers. It appears from Art. 43. *et seq.* that the resistance which friction opposes to the motion of a Machine is a constant retarding force; and where motion results, it must always be less than the constant motive force; consequently, the difference between the two is the effective, constant, moving, or motive force, and every constant force will produce an accelerated motion; if, therefore, a Machine actuated on by a constant force is put in motion, that motion will be continually accelerated without the employment of some regulator. It has been already observed, that in clocks this is commonly effected by a pendulum, which has a constant tendency to vibrate uniformly; and by means of a part called the escapement, the motive force or weight can only descend a certain portion every vibration; and the time of vibration being from the nature of the pendulum uniform, the motion of the wheels, hands, &c. become uniform also. This subject will be further illustrated in a subsequent Article; it is merely introduced here as being one of the class, and indeed one of the principal regulators of motion.

(65.) *On the fly.*—This consists of four or more radii projecting from a centre, and carrying at their extremities vanes of any convenient size, commonly so fixed that they may be adjusted to any angle; this is then fixed to some revolving part of the Machine, and is made to regulate the motion by the resistance the vanes experience against the atmosphere. This regulator of course ought only to be employed where uniformity of motion is the primary object, because if any force is intended to be transmitted, the motive force will have to overcome the resistance of the fly before it can transmit any further power, and thus an additional and unnecessary quantity of motive power is required. It is not therefore very commonly had recourse to, but it is in a few cases a useful regulator. Such as in the heliostat attached to equatorial telescopes, the common roasting-

lum.

The fly

Manufactures. jack, the striking part of a clock, and a few other Machines.

Fly wheel and governor. (66.) *Of the fly wheel and governor.*—In all the larger Machines where the primary object is a transmission of force, neither of the two former regulators can be employed, and recourse is then had to the fly wheel and governor; the former being intended to prevent any great and sudden irregularity of motion, by absorbing any additional momentum given to the Machine, which, on the other hand, it yields again when any deficiency of power is experienced on the motive side, or any additional force is to be overcome on the resisting side; while the governor is so contrived that if the acceleration of the Machine increases beyond a certain requisite degree, this acts upon the agent communicating the moving force, and modifies the supply, or otherwise on a different part of the engine to increase the resistance, and thus checks any undue degree of velocity; and, on the contrary, when the velocity is too small, it either acts to increase the supply of motive force or to diminish the resistance, and hence by the combined action of the fly and governor, a steady, uniform motion may be ensured, at least within certain allowable limits.

Causes of irregularity of motion. Several circumstances contribute towards rendering the motion of a Machine unsteady. When the motion depends upon the action of muscular power, whether of men or animals, it is obvious there must necessarily be variability of exertion. If the first mover be the wind, nothing is more proverbially inconstant; if water be the agent, certain irregularities of force and velocity are incident to rivers, and indeed to most supplies of this fluid. In the steam-engine, again, the elastic power of the steam depends upon a proper attention to the fire, to the supply demanded, &c.; the greatest irregularity would therefore ensue, but for the highly ingenious contrivances we are about to describe. Moreover, it is not only irregularity in the power of the first mover that is to be guarded against; a much greater cause for irregularity of motion is found in the variable resistance to which the Machine is exposed. A shaft of an engine is frequently opposed in its different parts to different works, and means will be found described, in the section *Engagement and Disengagement of Machinery*, for throwing these separate works occasionally out of gear, so that one operation may be suspended while the general action of the Machinery is continued. A considerable difference of resistance is thus created, which would greatly interfere with the admirable application of Machinery to the endless variety of uses to which it is now adapted, had not the ingenuity of the mechanic devised a remedy by the simple but admirable contrivances of the fly wheel and governor.

The fly wheel consists of a heavy rim of metal fixed and balanced on its axis, and so connected with the shaft or some other part of the Machinery, as to turn round with it with considerable velocity, but with greater or less according to the nature of the work to be performed by the Engine. The momentum or inertia that may be thus accumulated is so great that it will continue the motion of the Machine for a considerable time when even the whole impelling force is withdrawn, and is therefore admirably calculated to correct the comparatively smaller irregularities to which we have alluded above, not only in the motive power, but also in the resistances to which the Machine is opposed, and such again as arise from the conversion and reciprocation of motion; as also in the temporary application of very great resistances, as in the operation of rolling iron, &c. In the

Machinery. latter case it serves not entirely as a regulator, but rather as an accumulator, for without such a magazine of power as is thus furnished, it would be impossible by the simple power of the Machine itself to produce the requisite degree of force. In fact, it is an indispensable appendage in a very great number of Machines, and it will therefore be necessary that we enter here at some length into its theory, as we have in a previous article into its construction; for it is obvious, that a wheel weighing many tons and of great diameter, viz. from twenty to thirty feet, revolving with considerable velocity, must not only be formed and framed with great regard to strength, but likewise employed with great skill and care, lest the centrifugal force, and consequent strain of the rim on the arms, should exceed that of the cohesion of the parts, and be thus destroyed by its own power. Two instances of this kind have fallen under the observation of the writer of this Essay, one at Merthyr Tydvil, and a second at the King and Queen iron-works, Rotherhithe; in both instances parts of the wheel of several hundred weight were forced through the roofs of the buildings; and in the latter, one fragment, weighing sixteen hundred weight, was projected to a distance of two hundred feet, but fortunately in both cases without producing personal injury.

Theoretical Examination of the Action of the Fly Wheel.

(67.) In order to ascertain the nature and advantages of the operation of the fly wheel, we might separate the question into two cases: 1st, where the motive power is constant, or rather continuous, as in the water or wind-mill; and 2dly, where it is periodic, as in the successive strokes of the piston of a steam-engine. But by making our comparisons rest with the number of revolutions, or number of strokes, and rejecting thereby the slight acceleration which takes place during one revolution or one stroke, that is, conceiving the force to act *per saltum*, we may reduce these two cases into one, and at the same time very much simplify the investigation.

Theory of the fly wheel. Confining ourselves at present to the steam-engine, and disregarding at first the resistance and friction of the parts, considering moreover the fly wheel as attached immediately to the crank shaft, it is obvious that every reciprocating double stroke of the piston will produce one revolution of the fly; if, therefore, l denote the length of the stroke in feet, r the radius of the wheel in feet, and $\pi = 3.1416$, the relative velocity of the circumference of the wheel and piston will be as $\pi r : l$; if also the weight of the wheel, supposing it all collected in the rim, be denoted by w , and the pressure on the piston by p , the relative momenta of the two will be as $\pi r w : p l$. In this state of the question, however, an acceleration would go on indefinitely increasing, not, as in the force of Gravity, at every instant, but at every successive stroke of the piston in the steam-engine, and at every revolution of the shaft in the wind or water-mill, because we suppose no acceleration during the revolution, but a fresh access at every complete rotation. According to this view of the subject, both the velocity of the piston and the circumference of the fly will continue to accelerate, preserving always the same proportion with regard to each other, till the velocity of each is such as is best suited to the power of the engine and to the nature of the work to be performed. After which a resistance being thrown on, equal to the motive power or pressure on the piston, the acceleration will cease, and the

Manufac-
tures.

motion of the engine, while the motive power and the resistance are the same, will continue uniform.

(68.) In order now to ascertain the amount of accumulated power in the circumference of the wheel, we have only to consider the ratio of the two momenta, viz. $lp : \pi r w$, and we shall have for its measure $\frac{\pi r w}{lp}$; that is, a

flow received at the circumference of the wheel would exceed that given by the piston in the ratio of $1 : \frac{\pi r w}{lp}$; but

if a resistance to the motion of the wheel be introduced nearer to the axle of the wheel than at its circumference, the effect of the wheel's momentum will be still further increased, in proportion as the point of application is nearer to the axle; that is, calling that distance d , the

measure of the wheel's effect will be $\frac{\pi r^2 w}{lp d}$. All other

things being the same, therefore the power of the wheel to overcome a resistance will vary as r^2 ; and if every thing is constant but the weight, its power will be as w .

Hence it has been said, it is preferable to increase the radius, preserving the weight, than to increase the weight, preserving the radius, which is theoretically true, but practically false; for by increasing the radius and preserving the weight, we must reduce the dimensions while we increase the strain upon the arms, so that following such a rule without considering this side of the question, would unquestionably lead to the destruction of the wheel by its own centrifugal power, and probably to the sacrifice of many lives. Such accidents we have seen do sometimes occur, and how many of them may be due to those kind of theoretical doctrines which are only true on paper, it is impossible to say. It is perhaps quite within the reach of Mathematical rules, supposing the weight and velocity of the wheel to be given, to compute the requisite dimensions of the arms; but practical men at the present day will find a much better guide in studying those engines of the best performance, which are generally the result of numerous practical deductions, and frequently of dear-bought experience.

To estimate the reduction of velocity in the fly wheel, and consequently in the Machine, from either a temporary suspension of the motive power, or the introduction of a temporary increased resistance, we must consider the ratio between the two momenta. Suppose, for example, $lp : \pi w r : 1 : n$, and the piston or the crank by which it acts, ceased its operation for one stroke, i. e. the down or up stroke, then it is obvious, a momentum equivalent to 1 would be absorbed by the resistance to which the Machinery is opposed, and the velocity of the wheel reduced in the ratio of $1 : \frac{n-1}{n}$,

or as $1 : \frac{\pi w r}{lp} - 1$, or as $1 : \frac{\pi w r - lp}{\pi w r}$; and if instead of the suspension of action being during a stroke, it is only during a small part of it, as actually happens every individual stroke, and supposing this suspension to occupy only the $\frac{1}{q}$ part of time in which the stroke is made, then the change in the velocity of the wheel will be as $1 : \frac{qn-1}{qn}$, which will be nearly inappreciable when the product rw is of any considerable magnitude. It is not so easy to estimate the check given to the

velocity by the introduction of a temporary resistance, it being impossible in many cases to form any idea of its amount; as, for instance, the resistance produced in a rolling mill by the introduction of the iron, and in many other cases. Here, therefore, we can be guided only by practical experience. But when the resistance is of such a nature that a momentum equal to it can be expressed, the reduction of velocity may be computed on similar principles to those of the suspension of action in the motive power, that resistance as transferred to the piston being in effect equivalent to such suspension.

At present the fly wheel has been considered as attached to the crank shaft for the sake of simplifying the illustration of its action, but it is obviously the same in principle, although different in amount, when it is attached to any other part of the Machinery. We have, therefore, only to determine the relative velocity of the piston and the rim of the fly, to multiply the one by the pressure on the piston, and the other by the weight of the wheel, which will give the relative momenta, and hence the computation may be made as above directed. Suppose, for example, the piston of a steam-engine to move with a velocity of $3\frac{2}{3}$ feet per second, and the velocity of the rim of the wheel at 8 feet per second, the pressure on the piston to be 3000 pounds, and the weight of the wheel 10 tons, or 22,400 pounds, and that the piston is ineffectual during one-tenth of the stroke, required the consequent change in the revolution of the wheel.

According to what is above stated, we have for the ratio of the momenta $1 : \frac{22400 \times 8}{3000 \times 3\frac{2}{3}} : 1 : \frac{1792}{110}$ or $1 :$

16.3 nearly, and since $q = .1$, we have $\frac{16.3-1}{1} = 16.2$,

that is, the irregularity of motion will be 162 to 163.

(69.) In the foregoing remarks we have alluded to the question whether it be better to enlarge the radius and preserve the weight, or to enlarge the weight and preserve the radius, when it is wished to increase the momentum of the wheel. We have seen, however, that a certain limit cannot be safely exceeded in the first case, from the tendency that would be brought on to fracture the arms, and even the rim itself, by the increased velocity; and, on the other hand, by increasing the weight and retaining the radius, we should bring a greater strain on the axle, and an additional quantity of friction, so that neither the one nor the other would be had recourse to by the well-instructed engineer, who would doubtless think it preferable to increase both the weight and radius, and by this means give additional strength to resist the additional velocity.

There is also another way in which the momentum may be increased, which is by giving an additional angular velocity to the wheel, but here again we are limited by considerations of strength; for a wheel which has only the proper dimensions for a velocity v , might be destroyed if we gave it a velocity $2v$, so that we are not enabled to proceed on this principle *ad libitum*; and unfortunately it is useless to attempt to give theoretical rules for circumscribing the limits; practical results are the best guides; it may be humiliating to the Mathematician to be told, that his comprehensive science will not reach such questions, but it is not the less true.

We have thus three different ways of producing the same momentum; that is, denoting the angular velocity of a wheel by n , its weight by w , and its radius by r , the momentum is proportional to nwr , each of which quan-

Machinery.

Manufactures. tities may be taken at pleasure within practicable limits. In some instances where the opportunity has offered, experiments have been made to ascertain, in cases where the numerical expression for the momentum is the same, which of two different wheels was preferable. An instance of this kind occurred in His Majesty's Dock-yard at Portsmouth, where there were two wheels of the same weight, but of different radii, the angular velocity of the two being however so proportioned that their momenta were the same, and the result was, that one wheel answered better than the other for one species of work, and the contrary in a different kind of work. In fact, although numerically expressed the same, there is a difference in the two cases, in what may be denominated intensity of action, which is beyond the reach of numerical expression; and hence the inefficiency of Mathematical investigation in this and some other questions of great practical importance.

Governors. (70.) *Of governors.*—We have above described the important services performed by the fly wheel as a regulator of the velocity of mill work, and its action as a corrective of the irregularities to which Machinery is subject. Its effect is, as we have seen, that of a reservoir of power, so that any sudden increase or decrease of the work to be performed, or, what is nearly the same thing, any sudden increase or decrease of the motive power, when of short duration, but little affects the velocity of a Machine: if, however, these changes exist for any length of time, the fly wheel loses its effect, and the Machinery acquires an accelerated or retarded velocity. In order to obtain a perfect uniformity under these circumstances, it was necessary that the velocity of the Machine should govern the supply of motive power, and the means of accomplishing this is admirably attained in the beautiful contrivance termed the governor, which consists of one or more balls revolving with the Machine, and by the action of the centrifugal force moving into different positions at different velocities, and the motion thus obtained is conveyed by a system of Machinery so as to act on the supply of motive power, or on the amount of resistance.

Plate iv. This regulator acting on the latter principle was applied many years ago to wind-mills, in a contrivance called the *lift tenter*, which was employed to correct the effect of the irregular action of the wind, in forcing the corn rapidly through the mill without being sufficiently ground. This Machine, with part of the stone framing with which it is connected, is represented in plate iv. fig. 1. To the stone spindle there are fixed four arms, *a a a a*, and to the hollow cylinder *c*, which is loose on the spindle, are attached four similar arms, *b b b b*; the pendulums, *d d d d*, are suspended from the arms *a a a a*, and have holes near their lower extremities, through which the arms of the loose cylinder pass. When the mill is at rest, these pendulums hang vertically; but when in motion by their centrifugal force they assume an oblique position, and that obliquity is increased in proportion to the velocity, and proportionably raises the loose cylinder *c*. This acts upon one end of a lever, which is connected with the clove upon which the bridge of the stone spindle rests, and accordingly depresses the upper mill-stone as the wind is strong, so that the corn is in all cases sufficiently ground, and at the same time greater resistance being produced to the motion of the stones, the velocity of the mill is also in a great measure regulated.

The most simple form of the modern governor is

shown in fig. 2. *A A* is the vertical axis, which is constantly revolving by the Machinery: at *a* two arms or pendulums are jointed, each carrying at its extremity a heavy metal ball, *b*; from the pendulums proceed two chains or iron rods, *d d*, which suspend a collar, *e*. This slides freely up and down the axle, and has a groove formed all round it, in which the end of a fork *D* is received; and thus the rising and falling of the collar produces a corresponding motion of the end of the lever *D*, which acting through other levers, according to the nature of Machine, regulates the supply of motive agency, whether steam or water.

Machinery.
Fig. 2.

On the Transmission and Conversion of Motion.

(71.) Referring to what has been already described relative to the operation of first movers, it will appear that their effort is always rectilinear, but when they act tangentially on the circumference of a circle, their immediate effect is to produce rotary motion, and in the application of the forces thus obtained, it becomes necessary to transmit the action of what may be called the second mover, to other parts of the Machine; in the course of which rectilinear motion is sometimes required to produce another rectilinear motion, in the same or in a different direction, and with the same or with an increased or diminished speed. In like manner one rotary motion is sometimes made to produce another rotary motion, either in the same or in a contrary direction, and with increased or diminished speed. In other cases rectilinear motion is made to produce circular motion, and circular motion rectilinear; reciprocating motions, both rectilinear and circular, are made to produce continuous motion, and continuous motion reciprocating, &c.

To describe the different ways by which these various effects are produced, would be to analyze nearly every species of Machine that has ever been invented, and would be inappropriate in this place. Our object here is merely to illustrate the more simple means which are had recourse to in connecting the first with the second mover of a Machine at the impelled point, and the last action upon the working point. For the rest, it is conceived that the great variety of contrivances by which the direction of motion is changed in the processes of a Manufactory, in fact all the minutiae of those operations, which the ingenuity of the mechanist has devised for particular purposes, will be best explained individually as they occur in the description of the several engines and processes which it will be our business to illustrate in a subsequent part of this Treatise.

The conversion of rectilinear motion from one direction to another, either with increased or diminished velocity, is generally effected by means of pulleys and blocks, and is too obvious to require any description.

Continuous rectilinear motion is converted into circular motion by means of a descending weight attached to a cord wound about a barrel or axle, as in the case of clocks; the action of the wind on the sails of a wind-mill, and the action of water on the floats of an under-shot wheel, are other instances of this kind which require no particular illustration in this place.

(72.) *To convert a reciprocating rectilinear motion into a continuous circular motion.*—This is a question of great importance in practical Mechanics, and was one of the difficulties which Watt encountered in the early progress of his important improvements in the steam-engine. It is now commonly effected by means of a crank, but

Manufactures.

Action of the crank.
Fig. 3.

other methods are employed for the purpose as described below.

(73.) *Of the crank.*—Let it be required to give a rotary motion to the wheel A B C D, (fig. 3,) about its centre O, by means of a reciprocating, vertical motion of the end of the rod Q F. Conceive the vertical rod Q F to turn freely on a pin at its upper end, and also at F, in any part of the wheel A B C D, or attached to a crank as in the figure, so as to have a perfectly free motion at each end. Then it is obvious that while the point Q ascends, it will pull on the lever F O, till the point F is vertical, and thus produce a motion in the wheel; at that instant the rod Q F begins to descend, and pushes the lever or crank, till it is again vertical below at E; when the rod Q F begins again to ascend, and again drags the lever with it, and by this means gives continued rotation to the wheel. At the two vertical points, E and G, it is obvious that the rod Q F has no mechanical effect, but the inertia of the wheel acquired by its previous motion carries it over these dead points, and the rotation becomes continuous.

It is obvious that the action is different in different parts of the circumference, and consequently that the wheel is unequally urged forward, and hence the important service of the fly wheel described in article (67.) which serves to equalize all these irregularities.

Fig. 4.

In order to investigate the action exerted tangentially on the wheel in any part of its rotation, let C B, fig. 4, represent the vertical line on which the lever acts, and D the position of the crank in any part of its rotation: let also α represent the angle D C O, that is, the angle of the rod's inclination when the crank is at D; let also c denote the angle D O E of position of the crank, and P the vertical power of the rod. Resolve P into the two forces C D, D G, the former being $C D = P \sec \alpha$. Draw D F perpendicular to D O, and let fall C F per-

pendicular to D F, then will F D represent the tangential force at D. Machinery.

Since C F and D O are parallel $D C F = (\alpha + c)$ and we have

$$\text{force in D F} = P \sec \alpha \cdot \sin (\alpha + c)$$

$$\text{or force in D F} = P (\sin \alpha \cdot \cos c + \sin c \cos \alpha) \sec \alpha.$$

In order to exterminate the sine and cosine of the angle α , let the length of the rod C D be to the radius O D as $n : 1$. Then D G being common to both triangles,

$$\sin c = n \sin \alpha \text{ or } \sin \alpha = \frac{\sin c}{n} \text{ and } \cos \alpha =$$

$$\sqrt{\left(1 - \frac{\sin^2 c}{n^2}\right)} = \frac{\sqrt{(n^2 - \sin^2 c)}}{n}.$$

These substitutions being made, we get the force in D F

$$= P \sin c \left\{ \frac{\cos c}{\sqrt{n^2 - \sin^2 c}} + 1 \right\} \text{ which is of course easily}$$

converted into numbers.

And in a similar way we find the additional strain on the axis of the shaft, and consequently the friction to be as

$$P \left\{ \cos c \mp \frac{\sin^2 c}{\sqrt{(n^2 - \sin^2 c)}} \right\}$$

the lower sign being used after the rod becomes a tangent to the circle, that is, when C F falls on the other side of C D, and the upper sign for the position shown in the figure.

The following Table has been computed by Mr. Tredgold, showing the variable power of the crank in different parts of its rotation. The length of the crank is considered 1, and the length of the rod is taken 2, 3, 4, &c. to 7, and the forces in the tangent computed for each case at different angles varying from 0° to 180° .

TABLE.—Showing the variation in the force of the Crank from the formula $\text{Force} = P \sin c \left(\frac{\cos c}{n^2 - \sin^2 c} + 1 \right)$; P being considered as unity.

Men at a windlass.

(74.) The action of a man at a windlass is somewhat similar to the above. The great effort of a man in such case is in pulling and pushing, and may be in some measure assimilated to the pulling and pushing power of the rod in the above example. Commonly when men are thus employed a double crank is used, and these are generally placed diametrically opposite to each other; but as this brings the weak point of both cranks on at the same time, they have been sometimes placed at right angles with each other. But not being commonly adopted, we may conclude that practice has decided in

favour of the former position. The best length of crank for men is considered to be about 16 inches.

(75.) Another method of converting a reciprocating vertical or rectilinear motion into a rotary motion is shown in fig. 5; this is called the *sun and planet wheel*. Here a toothed wheel, A, is fixed centrally with the large wheel to which the rotary motion is to be conveyed; B is another toothed wheel, fixed firmly to the end of a vertical rod, C C, so as not to be allowed to turn; and a strong link connects the centres of the two wheels in order to prevent their separating. If now we conceive Sun and planet wheel.

Manufactures. the shaft D to be turned round in the direction of the arrows, it is plain that the wheel B will revolve round the wheel A in the same direction, and thereby elevate the rod CC, till the wheel B is found at the top of the wheel A; when by continuing the motion of the large wheel, the wheel B must necessarily descend to its first position, and so on continually. This, however, as we have stated it, is converting a rotary into a vertical motion; which was done, because in this form its action appears to be more easy to comprehend. We have only now, however, to consider the rod CC to be first put into motion, when it necessarily follows that it must by its action give rotation to the wheel A, and to the large wheel to which it is fixed.

It was by this means Mr. Watt converted the reciprocating motion of his first steam-engines into a rotary motion, not however entirely as a matter of choice; he would have preferred the crank, but was prevented using it by a patent which had been taken out by another Engineer. There are cases, however, in which it may be still used with advantage, although the crank has now entirely superseded the use of it in steam-engines.

Rotary motion is transmitted and converted into rotary motion in the same or other direction in a great many ways, viz. by bands, straps, wheel and pinion, bevel gear, and with various changes of speed; but these are generally so simple and so common as to be familiar to every one, we shall therefore only select one or two cases, and those only where change of direction or change of speed make them rather peculiar.

(76.) *By bands or straps.*—One obvious, and perhaps the earliest method of transmitting rotary motion, with or without a change of speed, is by bands or straps, of which we have numerous common examples. Fig. 6 shows a motion of this kind, in which by having a series of pulleys, or of grooves, in one common pulley, corresponding with others in another such wheel, so as to preserve always the same length of band, a great variety of speed may be obtained by merely shifting the band from one pair of opposite grooves to another opposite pair.

The bevel gear furnishes a method of changing the direction of motion from one line to another, forming any angle with it. See what has already been said on this head, section (33.); see also fig. 2.

(77.) *Alternate cones* are sometimes used for changing the velocity of motion, when this requires to be gradually and uniformly accelerated. Here one of the cones, A, (fig. 7,) gives motion to the other by a belt, which is carried along by a guide, by which means the motion is accelerated or retarded at pleasure, or retained constant while the guide remains stationary.

Another method of changing velocity is shown in fig. 8. The two wheels A and B are fixed on the same axis, a little apart from each other; the other two wheels, C, D, are cast together, and run on an axis with the means of slipping them a little backward and forward; when C D is thrown back on its axis, the teeth of the wheel C engages those of the wheel A, while those of B are thrown beyond the wheel D, and a certain speed is the result of this action; but by sliding the wheel C forward, the teeth of the wheel B engage those of D, and a different velocity results, as is evident.

(78.) The conversion of continuous rotary motion into a reciprocating rectilinear motion, may obviously be effected by merely inverting the methods already described for converting a reciprocating rectilinear motion

into a continuous rotary one, but they are not commonly employed in practice. The two following have, however, been occasionally used for either purpose, accordingly as circumstances required. We shall here speak of them as a means of converting a rotary into a rectilinear reciprocating motion.

Conceive a pinion A, fig. 9, to be made to give motion to the wheel B B', and this again to give motion to the equal wheel C C'; to the axles of these, beyond the beam LL, are fixed the cranks D D', and to pins at their extremities are the suspended rods G G' perfectly free to move. These are fixed to the transverse bar H H, from the centre of which proceeds the rod I to which the vertical motion is to be given. Here it is obvious, that when the pinion A is put in rotation in the direction of the arrow, the motion of the two wheels, and of the cranks D D', will have the directions shown by the arrows between B and C, which will bring the ends D D' of the arms towards B and C, and then towards B' C', and thus by the alternate closing and opening of the two points D D', as well as by their actually ascending and descending, a perfectly rectilinear motion will be given to the rod I.

(79.) *Another Method.*—Conceive the wheel A B, fig. 10, cut with interior teeth to be fixed in its place, within which the interior wheel C D, with exterior teeth, and of half the dimensions of the fixed wheel, is made to revolve. Let a pin truly turned project from its rim exactly opposite its extreme circumference. Then shall this point, by the revolving of the small wheel, ascend and descend vertically in the diameter of the larger wheel, and, consequently, will give to any rod which is attached to it the same vertical or rectilinear motion. The result of this operation is not so obvious as in the former case; it may not, therefore, be amiss to give the reader a geometrical demonstration of the truth of the proposition. This may be done very simply as follows.

Let $aedf$ (fig. 10) represent the fixed wheel, and $ac, b'c$, the interior revolving wheel in two positions, being in the former at the extremity of the vertical diameter ad of the larger fixed wheel, it is to be demonstrated, that when this wheel comes into any other position $b'c$, the point a in its circumference will always be found in the diameter ad . Now to prove this, all that is necessary is to show, that the arc $b'a'$, in the second position intercepted between b' and the vertical ad , is always equal to the arc $b'a$ of the greater circle. Take oo' the centres of the circle in its two positions, join $b'c$, $bo'a'o'$, then it is obvious, that $ba = b'a'$, and that the angle $boa = \text{angle } b'o'a' = 2b'ca$, because an angle at the centre is double the angle at the circumference; but the length of circular arcs are as the angles they subtend multiplied by their radii. Hence the angle of the larger circumference being half that of the smaller, but its radius double the radius of the smaller, the arcs themselves are equal, that is, in all positions $b'a' = ba$, consequently, the point a is always found in the vertical ad .

OF THE FORM AND CONSTRUCTION OF MILLS.

(80.) In the preceding chapter the principles of constructing the different parts of mill work have been illustrated; it remains for us in this to show these elementary parts combined into the form of the mill itself, that is, we have now to explain the manner in which different powers are enabled to give rotation, and to act upon

Machinery

Fig. 6.

Fig. 7.

Fig. 8.

Manufac-
tures.
Construction of
mills.

the impelled point of an engine but at present, without inquiring into the nature of the engine itself, or of the work it is intended to perform. A wind-mill, for example, is the same in its principle whether it is intended to pump water or grind corn, so likewise a water-mill may be converted to the purposes of boring, sawing, rolling, grinding, &c.; a horse-mill, also, as far as its power extends, may be employed for any of the above purposes; and so, also, may the steam-engine. It will, therefore, be understood, that the term mill, as used in this chapter, implies only such a form of Machinery, as will enable the five principal classes of first movers to produce rotation; this rotation once produced, it may be applied of course to the impelling of any engine, or to any manufacturing processes to which its power is competent.

Under this arrangement we have to describe the hand-mill, tread-mill, horse and cattle-mill, wind-mill, and water-mill; and the

Steam-engine, which is also but a mill, according to this acceptance of the term, will be treated of in the following chapter.

(81.) *Hand-mill*.—It is probable that this is a Machine of the highest antiquity. We can scarcely conceive a state of civilized society in which some process was not had recourse to, to prepare corn for the formation of bread, and there can be little doubt, whatever may have been the date of the invention of horse-mills, or of wind and water-mills, that they were preceded by hand-mills. When the World was but thinly peopled, and every family formed almost a distinct community, there was no call for a greater power than what might be furnished by one or two persons working at a mill; and, accordingly, this seems to have been the means adopted even so late as the time of Christ, who says, *Matthew*, ch. xxiv. ver. 41. "Two women shall be grinding at the mill, the one shall be taken and the other left." As population and civilization proceeded, and the advantage of division of labour began to be in some measure understood, it was found desirable that the reduction of corn to flour, (which was doubtless the first intention of the mill,) should be attended to by certain persons for a general supply to the community, and then horse-mills, or cattle-mills, were constructed; and even to this day in the East, mills of this description are nearly the only ones employed. A recent fire at Constantinople which destroyed more than 1500 houses, burned down also 120 horse-mills; a proof of the very little advance which has to this day been made in the progress of the Arts in that ill-fated Country. The water-mill is supposed to be of Greek invention, but the inventors of that useful Machine, the wind-mill, are not known. Wind-mills are, by Montucla, supposed to have been used by the Dutch in the VIIIth or IXth Century, but others have imagined that the idea of their construction was derived from Asia in or about the XIIth Century.

Our business, at present, is to describe the hand-mill, which although wholly superseded in its application to grinding flour, except in very particular cases, is still useful for some purposes where great power or great supply is not wanted, as for grinding malt in families, and for some other domestic purposes. It has been also till lately, and is perhaps at present, employed in some prisons for furnishing a means of prison labour; these, however, are now greatly if not entirely superseded by the much more convenient and appropriate engine the tread-mill.

Various forms of hand-mills have been devised, of which a remarkable one is described in Gregory's *Mechanics*; in which the crank is worked by a rowing motion, the most advantageous way of applying a man's strength. It is an old idea, being described in Bockler's *Theatrum Machinarum*. This contrivance seems only to require a fly wheel to make it a complete Machine.

(82.) A very simple hand-mill is represented in plate v. fig. 1, which requires but little description. *AB* is a strong wooden frame; *W* a face wheel running in proper bearings at *P.P.* This wheel is turned by the winch *E*; the teeth of the wheel *W* engages with the staves of the trundle on lantern *T*, and on the spindle of this is fixed the revolving or upper stone of the mill, not seen in the figure, the stones being enclosed in the case *C*. The corn is first placed in the hopper *H*, whence it passes to the stones, and being ground is carried out at the spout *D*.

Hand-mills are employed in various processes for domestic purposes, and by retail tradesmen for grinding coffee and malt, pulverizing sugar, and for many other uses; but their constructions are generally so simple and so well known, as scarcely to require notice in this place. Some other hand-mills, or Machines of equivalent action, will be explained in subsequent sections in describing different mechanical and manufacturing processes, and in particular we refer to Rustal's hand-mill for grinding and dressing corn, under the section Corn-mill.

(83.) *Tread-mill*.—This is a new and very useful invention, for which we are indebted to Mr. W. Cubit, Civil Engineer. Its utility, however, depends rather upon the purposes to which it is applied than to any intrinsic value it possesses as a mechanical construction. We have seen (§ 12.) that it is impossible to apply human strength as a first mover of Machinery without a great pecuniary sacrifice; consequently, we must not look to the Tread-mill as an economical mode of obtaining mechanical power, as far as expense is considered; but there is a higher order of economy, which is (if we are not much mistaken) administered to by this application, viz. the correction and improvement of the morals of the idle, vicious, and disorderly part of the community. Many of this class of persons are so debased and degraded by the courses of life they have led, that they would prefer, perhaps, the dreary abode of a prison in idleness to that of living by the sweat of their brow, and to such dispositions nothing can act as a better corrective than the Tread-mill. Here they must work, no shifting or contriving will allow them to lie by and throw their share of labour upon their more willing companions in misery; and it is accordingly found by the reports of the Governors of various prisons in which this uncompromising Machine has been erected, that few who have had a full trial of this labour are willing to expose themselves to it a second time. If they must work when in prison, they, of course, had better work out of it, and this appears to have been the actual result in many cases. See *A Report of the Society for the Improvement of Prison Discipline*, 1823.

The usual form of the Machine is a long wheel, varying from eight or ten feet to twenty or more feet in length; and a number of these are sometimes united by couplings to a very great length; the usual diameter is about five feet or about sixteen feet in circumference, furnished with twenty four leaves or steps, each of course of eight inches, and within which, at a sufficient

Machinery.

Simple hand-mill.

Tread-mill.

Manufac-
tures.

depth to leave a foot-hold, it is close boarded, at least in some cases, in others, and those more common, it is left open for the sake of air. Each separate wheel has a bearing at one end or at both, but commonly only at one, the other end being supported by a coupling with the bearing end of the next wheel, and so on, in some large prisons to the number of eight or ten in one continuous line. The number of persons on a wheel depends of course upon its length. In Cold Bath Fields' prison there are eight triple wheels, each three holding thirty or thirty-six persons. In general, between each wheel is a partition reaching above the heads of the prisoners, who are not allowed to hold conversation while at work. The Governor of a prison is thus enabled to keep separate and classify his prisoners, which is a great advantage. When the whole shaft is made into one by couplings, as above described, the velocity of rotation must of course be the same in all; but by means of greater relays in one class than in another, the degree of labour may be modified, or the wheels on which boys and women work may be made of less diameter, and, of course, the rise at each step proportionally less. The common practice is to have the part in front of the wheel boarded up from above its centre, leaving the bottom part open where the steps are successively presented to the unwilling tread of the prisoner; the time on the wheel is usually about half an hour, but each prisoner is relieved singly, and not in a body as formerly.

Description
of a Tread-
mill.

(84.) The construction of this Machine is so simple as scarcely to require a delineation; we have, however, given a perspective view of one, consisting of a triple combination, in fig. 2, plate v. This is shown as elevated about eight or ten feet above the level of the prison yard under a shed. This elevation is recommended for the sake of giving more air to the prisoners when at work; and the part under the floor is convenient for carrying on other prison work, as picking hemp, &c. for prisoners unable to work at the wheel. Each wheel is about eighteen or twenty feet long, and separated from the adjacent one by a space of about two feet. At each end, and between every two wheels, is a short flight of steps, serving for the prisoners to ascend to their work. The wheel being about five feet in diameter, and the lower part a foot above the floor, the centre of the wheel, or treading part, is thus raised three and a half feet. Above the tread part of the wheel, the latter is shut in by boards; rather sloping from the front, and along the whole length, runs a hand rail for the prisoners to steady themselves by while treading.

Arrange-
ment for
conducting
the work.

(85.) The order of working is as follows: each wheel holding ten or twelve prisoners, fifteen or eighteen are made to form one gang, twelve of whom, supposing the larger number, ascend by the steps on the right, and move on, one by one, to the other end, till all twelve are in their places, the other six sitting down in front of the wheel, with their faces towards the yard. The mill is now set in motion by the weight of the persons upon it, and by means of a regulator its speed is made to be about two revolutions per minute. After six revolutions, or three minutes, the man on the left hand of each wheel descends by the left-hand steps, and each man then slips on one place to the left, leaving room for one man on the right, which place is immediately supplied by the right hand man on rest. After another three minutes, or six revolutions, the left-hand man of each wheel descends, the prisoners on the wheel slip on

again one place to the left, the right-hand man on rest ascends, and so on during the whole time of work, the wheel continuing in motion from the beginning to the end of that period.

Machinery.

(86.) By this arrangement every man rests eighteen minutes and works thirty-six; or with ten men on a wheel, each one works half an hour and rests a quarter; but by changing the number of men on rest, or the number on the wheel, the ratio of working time and rest may be varied in any proportion. During all the time of work the most perfect silence is preserved, not only with the men on the wheel, but with those on rest, and thus much of that evil communication which formerly rendered our prisons little better than schools of crime is avoided.

Methods of
regulating
the velocity
of rotation.

In the Cold Bath Fields' prison there are eight triple wheels similar to that shown in the figure, for male prisoners only, which furnish hard labour for about 360 or 380 of this class of persons; and three separate mills, of single and compound wheels, for women. The eight mills in the men's division of the prison are ranged four on each side, in eight distinct yards, along the outside walls, the twelve shafts on each side being united in one long shaft by couplings. The end of each long shaft carries a bevel wheel working in another bevel wheel, on a vertical shaft, by which a vertical revolution is produced. The lower part of this vertical shaft, which descends below the ground level of the yard, works another horizontal shaft, and the motion is thus conveyed to a convenient part of the yard, where it gives motion to the regulator. This regulator consists of a vertical shaft rising about twenty feet above the ground level, and carries at its upper end a horizontal fly, with two arms and a governor. The fly itself is of the kind called the Venetian fly, consisting of a long rectangular frame, with shutters moving like those of the venetian blinds; the position of these blinds or shutters is under the control of the governor, by means of wheel work and levers, so that when the speed exceeds what is above stated, of two revolutions of the Tread-mill per minute, the governor balls fly open, and close the shutters, and by thus increasing the resistance check the velocity; and on the contrary, when the speed is too little the balls fall, the shutters open, the resistance is diminished, and consequently the speed increased.

With a Ve-
netian fly.

(87.) The above method of regulating the velocity of the wheel, however, although very effectual, has been objected to, as it requires a large and unsightly sort of apparatus; Mr. Cubit has therefore invented another method which is not seen outside the prison walls, as the fly generally is. This consists of three, four, or more large blacksmith's bellows, or bellows of that kind, but without valves, so that the receiving and delivering the air is effected at the same aperture or nozzle. One board of these bellows is connected with a crank worked by the mill, and the adjustment for regulating the speed is as follows. The nozzles or openings of the several bellows are brought into one plane in the face of a frame, and a slide with proper openings is made to pass over these apertures, and thereby to open or close them to any extent. This slide is connected with the governor in such a way, that when the speed is too great, the governor balls fly open, and thereby, by means of proper wheel work and levers, close the apertures, and thus increase the resistance to the entrance and expulsion of the air, by which the speed is reduced; and, on the contrary, when the motion is too slow, the governor balls

cipline.

close, the aperture is opened, the resistance diminished, and the speed increased. Mr. T. Bramah has given a full description of this apparatus as erected in Huntingdon gaol, with explanatory drawings, in the *Transactions of the Society of Arts* for 1827.

(88.) The construction of the Tread-wheel is exceedingly simple: it consists of one long iron shaft, and three or four (according to its length) cast-iron wheels of about three feet six inches in diameter, with twenty-four spurs or starts, like those of an under-shot water wheel, cast upon them; these starts or spurs are about eight or nine inches in length, and to them are screwed the boards of the same breadth, forming the leaves or steps of the wheel. The cast-iron wheels being first, however, securely fixed at their proper distances on the shaft above-mentioned. In some cases, each wheel has two bearings, but generally, when there are several in the same line, only one, the other end being supported by a proper coupling to the supported end of the adjacent wheel.

(89.) With regard to the efficiency of the Tread-mill as a mechanical agent, we have seen that the whole work at a maximum consists of a man lifting his weight about 12,000 feet per day; and assuming his weight to be 150 pounds, this amounts to only 1,800,000 pounds one foot high per day, or reckoning each man to work eight hours, 225,000 per hour, or 3750 feet per minute, and this is to be understood as the maximum, and as appertaining to the impelled point. Moreover, the prisoners assist themselves greatly by the hand rail, pulling up the body as a person does when ascending a steep staircase; and by so much as the arms assist, just so much is the effective power diminished, so that as a productive mode of employing a man's power, this Machine is entirely worthless, nor could it be made useful by any contrivance. An ingenious person of the name of Hayes sometime back took out a patent for converting the power used on the hand rail into efficient effect, by making these rails act as the steps of an upper wheel; but his invention was but a display of useless ingenuity, and has not, we believe, in any case been adopted.

(90.) As the leading intention of this Essay on Manufactures is to illustrate the nature of the productive Machinery of the Country, it will perhaps scarcely be expected that we should dwell longer on the present subject; but notwithstanding the Tread-mill cannot be classed amongst the productive engines, it is, if viewed in its proper character, a highly useful and simple Machine, at present very imperfectly known to the Public; and the management of it, even by those who have the charge of its working, has not been in all cases judicious.

Previously to the introduction of this Machine, the prisoners in many of our gaols led a life of entire idleness; in others, some works were carried on; and in a few, crank and capstan-mills were employed for breaking, grinding, and dressing corn, beating hemp, and a few other such processes. These, however, were generally ill-constructed, and no rule or uniformity could be observed in affixing a due share of labour to each individual.

These inconveniences, perpetually increasing with the increase of population, and a proportional increase of crime, led to the invention of the Tread-mill, which is perhaps better suited than any other Machine whatever to involuntary labour and prison discipline. Although weight is certainly not an actual and infallible criterion

of strength, it is perhaps the best that can be generally obtained; and as in this Machine the whole labour consists in a person lifting his own weight, the proportional quantity of work performed by each individual approximates nearer to his proportional strength, whether he be willing or unwilling to exert it, than could possibly be effected in any other way.

But while the means are thus afforded of apportioning to every idle individual his proper share of labour, it is important to restrain its use within due limits; when judiciously managed, prisoners have generally benefited in their health, and have left their place of temporary confinement in a better state than they entered it; but if too much is enforced upon them, they will not only be unable to continue the exertion, but injurious effects on their general health may be the consequence. And since in this particular Machine the amount of applied force is not measured, as in many others, at the working point, but at the impelled point, there can never be any necessity for an error of estimation. The amount of applied force is here, as in other cases of animal action, proportional to $t v w$, except that here w is constant, and it is therefore the other part of the product $t v$ which it is the business of those who have the management of these Machines to preserve constant. In general, it is recommended that a number, equal to one-half the number of persons on the wheel, should be relieved at certain intervals, by a relay in waiting of equal amount; so that of the whole number employed two-thirds are working, and one-third resting, the changes taking place successively as above described; but this proportion cannot always be maintained, for want of the usual number of prisoners, and then, of course, for want of sufficient weight, if the mill is performing any certain work, as grinding, dressing, &c., the wheel will move slower. In this case therefore, as the velocity is less the time ought to be greater, in order to preserve the product $t v$ constant; but as the number of working hours are not to be increased, the time must be gained by altering the proportional number forming the relays. For want of proper attention to this point a very unequal degree of labour has been exacted in different prisons, and much credit is due to the Committee of the "Society for the Improvement of Prison Discipline," for the pains they have taken to examine into all these irregularities, and to endeavour, while they are desirous of avoiding excessive labour, to provide means for ensuring such a constant amount of it, as shall be a sufficiently large demand on the muscular powers, to deter the idle and disorderly from paying a second visit to this unaccommodating Machine.

(91.) This Committee, after due examination, states, that 12,000 feet ascent every day ought to form a maximum, and 10,000 feet the minimum of labour; that the best rate is, as nearly as it can be attained in all cases, 48 steps per minute, each step being 8 inches, that is, 32 feet per minute ascent while actually working, and generally the relay of one-third seems best. But when this, for the reason above stated, cannot be, the Committee has, for the convenience of managers, caused to be constructed a sliding scale, very easy to work, by which the proper changes of relays may be immediately settled by the Governor, according to the number of prisoners he may have, whether in excess or in defect of the number for which the wheel was originally intended; they have also had constructed an instrument called a gyrometer for exhibiting the speed of the mill at any time, as also the

Machinery.

Maximum
and mini-
mum of
labour.

Manufactures. mean speed with which the Machine has been worked for any number of hours past. Both these instruments were invented and are sold by Mr. Bate, Instrument Maker, London.

Upon the whole, on a general view of the subject, and considering the great national object intended to be effected by deterring the vicious, while it administers to the improvement of their health and morals, as well as from the actual ingenuity displayed in its construction, our readers will not, we are persuaded, consider these observations inappropriately introduced in this place; and we cannot conclude them better than by giving the following Table of a list of all the mills of this description which were in actual work in our different

prisons in 1823, since which time many more have been erected, and much greater uniformity introduced into their management, both as regards their speed and the actual application of their power.

In this Table are given, first the names of the place and prisons, the number of persons forming the whole complement for which the mill is intended, the number of divisions or separate wheels, the proportion of the persons on the wheel, the velocity of ascent, hours of labour, nature of the work performed, and, in fact, every particular that can be interesting to the curious inquirer and the philanthropist or moralist, anxious for the amelioration of the more vicious classes of the community.

Horse and cattle-mills. (93.) *Horse and cattle-mills.*—We have seen (Art. 12.) that the employment of horses as first movers of Machinery is disadvantageous, in comparison with wind, water, or steam, as well in regard to expense as to convenience, in cases where any of them may be employed, and where the number of horses requisite for performing the work is considerable, but there are many kinds of work and manufacturing processes in which the power of one or two horses only is required; and in these perhaps the horse-mill has still an actual advantage over a steam-engine of so small a power, particularly if the work is not constant. As we have not in this place to describe the processes conducted by the power of the horse-mill, but simply to show its mode of action, and the means of obtaining rotation, we shall stand in need of very little illustration. The principal variety in the mode of communicating motion by a mill of this kind is, that in some the large cogged or bevelled wheel, which gives the first action, is placed above the shaft; and in others when the process is carried on below the level of the horse tread, this wheel is placed below; these two cases are shown in plate v. figs. 3, 4, 5, 6, and they constitute, indeed, almost the whole variety, while the processes carried on by the mill are not considered. For agricultural purposes, cattle are sometimes made to work in mills of this description, but not very commonly. In the East, oxen perform a great part of the work of these mills. In Egypt, they are used for drawing water, grinding corn, and in various other cases. In Constantinople, horses are more commonly employed than oxen; but in the Provinces, both Asiatic and European, the latter are the principal agents.

Pl. v.
Fig. 3, 4, 5,
6.

The action of the horse in these Machines being perpetually restrained by the circular path in which he walks, his power is not so great as when drawing in a direct line, but it is difficult to estimate the amount of this disadvantage. One rule, however, laid down by

millwrights, it will always be well to observe, which is, that the diameter of the horse-path ought never to be less than eighteen feet.

(94.) *Wind-mill.*—Wind is the least expensive of our Wind-mill. first movers; its power may also be said to be unlimited; but it is so irregular in its action, and ungovernable in its effects, that there are few uses besides the grinding of corn and pumping of water, that it can be applied to with any advantage.

By the term wind-mill is usually understood a mill for grinding corn; we shall, however, here treat it simply as a first mover of Machinery, describing only such parts as are required to obtain a rotary motion from the force of the wind, which rotary motion once obtained, may be applied to the grinding of corn, pumping or raising of water, or any kind of Machinery where extreme regularity is not essential to its good effect.

The invention of wind-mills is not of very remote date. According to some authors they were first used in France in the VIth Century; while others maintain they were brought to Europe in the time of the Crusades, and that they had long been employed in the East, where the scarcity of water precluded the application of that powerful agent to Machinery. Montucla, in his *Histoire des Mathématiques*, states that there is reason for considering that they were the invention of the VIIIth, IXth, or Xth Centuries. Vitruvius describes the water-mill, but does not mention the wind-mill, which he most probably would have done, if it had been known in his time; and as this latter Machine is known to have existed for some Centuries in Holland, where its use seems almost absolutely necessary, from the vast extent of land, level with the sea, which requires draining, and which of course precluded the use of water-mills; it is not, therefore, unlikely that it had its origin in that Country.

The vertical wind-mill, which is the most simple

Manufac-
tures.

Machine, and that most commonly adopted for applying the power of the wind to obtain a rotary motion, consists of an axle or shaft, placed in the direction of the wind, and usually inclined about ten or eleven degrees from the horizontal line. At the end of this axle four arms are fixed perpendicularly to it, which cross each other at right angles; and into these small cross bars are mortised at right angles, and other bars joined to them parallel to the length of the arms; so that they intersect each other in the manner of lattice-work, and form a surface upon which a cloth can be spread to receive the action of the wind. The planes of these sails are placed obliquely to the plane in which the four arms are situated, so that when the wind blows in the direction of the axle it does not impinge upon them at right angles to their surfaces, but obliquely; hence the effort of the sail to recede from the wind causes it to turn round upon its axle, and a rotary motion is thus produced, which by means of bevelled wheels, or common face wheel and trundle, is communicated to a vertical shaft to which is attached the Machinery to be put in motion.

Pl. vi.
Fig. 1, 2.

As the direction of the wind is perpetually changing, some contrivance is necessary for bringing the wind shaft and sails into their proper position, which is effected in two different ways. In the old mill (plate vi. fig. 1) termed the post-mill, the whole building which contains the Machinery is sustained upon a vertical post, and can be turned upon it by means of a lever. In the more modern wind-mill, (fig. 2,) the wind shaft is situated in a dome or cap, which revolves upon rollers, and can be turned into the direction of the wind, either by hand, or be made to adjust itself by the aid of a vane or rotating fan, situated at the extremity of a long horizontal arm, which lies in the same vertical plane with the wind shaft.

Post-mills.

(95.) *Post wind-mills* are necessarily limited in their size, as the whole building has to be moved for every variation of the wind. Fig. 1 is a section showing the interior of a mill of this description. The mill house is of a rectangular figure, the narrow front being presented to the wind. A B is the wind shaft, one end of which has a bearing on the beam C of the framing of the mill, and the other is supported in a similar way by a beam D; the part of the shaft outside the mill is larger, and made square, and has two square holes or mortises through it into which the whips or arms of the sails are fitted and made fast by wedges, *a a*. The wheel E E, which is termed the brake wheel, is attached to the wind shaft; it has a rim of wood, *b b*, on its circumference termed the brake, one end of which is attached to a fixed part of the mill, and the other, by means of an iron rod, to a lever *c d*, so that by pressing down the end of the lever the brake is made to bind upon the circumference of the wheel, and thereby produces such a resistance that the mill may be at any time stopped. The brake wheel is here represented on the old construction, *i. e.* the face wheel, which is supposed to work a trundle not shown in the figure.

The lower floor of the mill is made to receive the post P upon which the mill is turned round to face the wind. This post is a very strong tree, which is held perpendicularly by fixing it upon the middle of two long timbers which form a large cross upon the ground, and which constitute the base of the whole mill. The post is secured in its vertical position by four oblique braces, F F F F, which extend from the ground cross to the middle of it, leaving ten or twelve feet of the

upper part, which is made round, clear from the obstruction of the braces. This round part of the post rises up through the middle of the lower chamber, in the floor of which a circular collar is formed to the exact diameter of the post. At the upper end of the post is a pivot or gudgeon, which enters into a socket fixed to one of the strongest beams, G, in the middle of the upper floor; this beam must necessarily be very strong, as it has to sustain the whole weight of the erection. In this way the mill is made to turn freely upon the pivot, while the collet in the lower floor serves to keep it steady and in a vertical position. L is a ladder for the purpose of ascending to the mill; it is united by joints to the back part of the framing, and has a rope, M, fastened to the lower end, which passes in an inclined direction into the mill, so that by a lever, or pulleys it can be raised at pleasure clear of the ground. The ladder thus raised serves as a lever for turning the mill round, which is usually done by manual labour; sometimes, however, more force is necessary, and a small capstan is provided to draw a rope attached to the end of the ladder. This capstan is movable, and can be fastened at pleasure to any of the posts which are fixed in the ground for the purpose. When the mill is by these means placed in the desired direction, the ladder is let down to the ground, and its position being on the opposite side to that of the sails, it serves not only for ascent and to keep the mill steady in its position, but acts as a stay to resist the tendency of the wind to overturn it, an occurrence which sometimes happens in mills of this description. Post-mills being limited in size, are also limited in their application to Machinery, and, in England, they are seldom used for any other purpose than that of grinding corn. In Holland there are some made use of upon this principle, where the post upon which the mill turns is made of very large dimensions, and has a hole down the centre of it, through which a perpendicular axle passes to convey the power down to a building below. In this way the mill is applied to saw wood, to make paper, or any other purpose; the construction is, however, more complicated and less effective than the mill termed the smock-mill, where the head, or top, only turns round. This we shall now endeavour to describe.

(96.) *The tower or smock-mill* is the description of Tower or mill most commonly adopted in this Country, it being smock-mill. more convenient in its arrangement, and limited in its extent only by the difficulties attending the construction of sails of large dimensions. The power of wind-mills is of course so variable, according to the velocity of the wind, that it is difficult to make an estimate of it; the larger description of smock-mills are, however, considered to do the average work of six or eight horses. Fig. 2 is a representation of the upper part of a mill of this kind, AA are the sides of the stationary part or body of the mill, which is either built of brick or stone, or framed in timber. CC is a wooden curb attached firmly to the top of the wall, and upon which the rollers of the cap revolve. In brick buildings the fixing of this curb is a matter of some difficulty, as it is of essential importance that it should be perfectly firm and secure, and not liable to get loose from the continual jarring motion of the Machinery. It is commonly secured either to timbers built in the brickwork, or to long iron rods which extend to a considerable distance down the walls. BBB is the cap, or head, of the mill, which is made of timber strongly framed together, with a circular curb at

Fig. 2.

Manufac-
tures.

the lower part which revolves upon the one attached to the body of the mill. S S is the wind shaft, which is here represented of iron, the material now almost universally employed for that purpose: it has two sockets cast in the end outside the mill, into which the whips of the sails can be secured much firmer than in wooden shafts. It has two bearings on the framing, one in front, and the other some distance behind the centre in a similar way to the post-mill. The *pillows* of the bearings of wind shafts are usually made of brass, but sometimes of a peculiar kind of stone, called Nottinghamshire block, which is found to be a material much better suited to the purpose, as it works with little friction, and for a great length of time, which is of course a very important advantage where the replacement is a matter of much difficulty. The driving or brake wheel, D D, is bevelled, and made very commonly with two rows of teeth which act alternately with similar ones upon the bevelled crown wheel N, producing by this means a more regular motion than the common bevelled wheels. This mode of making the teeth is termed by millwrights *hit and miss*; it has already been described under article (27.) In modern mills both the brake and crown wheels are very commonly made of iron, and are attached to their shafts by the usual mode of keying. Sometimes wooden wheels are attached to the iron shafts, in which case arms are cast upon them, to which the wheels are bolted.

Of the
brake.

Fig. 3.

(97.) The brake does not differ much from those used in the post-mill. It consists of a rim of wood which passes nearly round the circumference, one end is attached to some part of the framing, and the other to the lever *b b*, seen in fig. 3. By means of a rope which passes over a pulley to the outside of the mill, a man from below is enabled to raise the end of the lever, and engage it with a hook, which is so constructed, that when the lever is thus raised the brake is clear of the wheel all round, and the mill is perfectly free to move. When it is necessary to stop the mill, the man by pulling the rope disengages the end of the lever from the hook, and allows it to fall by its own weight, which brings the brake down upon the wheel, and causes, by this means, so great a resistance to its motion, that there are very few cases, even in the highest winds, when a mill cannot be thus brought up.

The construction of the brake is a part of mill-making which should engage the particular attention of the workman, as their failure or fracture is often attended with the most serious consequences. In a sudden gale of wind, a mill, if allowed to work, would go at such a velocity, as not only to endanger the breaking of the Machinery but likewise the setting fire to the mill itself: under these circumstances the brake, of course, is the only means of stopping it. We are acquainted with an instance, where the handle of a brake having snapped in a gale of wind, the mill went at such a velocity, that one of the upper stones flew to pieces by the immense centrifugal force, and the miller, who unfortunately happened to be on the same floor, had both his legs taken off by one of the pieces, which afterwards passed through the side of the mill.

Plan of the
cap.

Fig. 4.

(98.) R R, fig. 2, is a ring of rollers which supports the whole weight of the cap, and by means of which it may be turned round upon the curb *cc*, with great facility, in any direction. The rollers *a a a a*, seen in fig. 4, which is a plan of the cap, are for the purpose of keeping it in its place; they are attached to the upper curb, and

revolve against the inner surface of the lower one, which is made very smooth and true; the framing in which these rollers are fixed, ought to be very firmly attached to the upper curb, as it has to withstand the whole force of the wind in its tendency to overturn the cap, an accident which has happened in high winds. By some millwrights rollers are not made use of in either of the above cases, the parts being made simply to slide upon each other; a method which is certainly less liable to get out of order, but it is attended with much more friction, and cannot be made use of for the self-acting caps, which would not have sufficient power to turn the mill under these circumstances.

Several methods are employed for turning the cap in its required direction; in all cases, however, the stationary curb has cogs formed upon its circumference, and an endless screw, or a pinion, which is attached to the cap, works in it. The mode of applying the force of a man to the pinion is shown in fig. 3; an endless rope passes round a wheel *a* and to the bottom of the mill; this has a pinion *b* upon its axle, which engages a toothed wheel on another axle *c*, to which is fixed the pinion required to work in the cogs of the stationary curb. In this way a man outside the mill can turn the cap round with great facility in any direction.

The mill shown in fig. 2 has the self-adjusting cap which is turned round by the force of the wind acting upon the flyer or fan, and is so contrived that it always presents the sails in the proper direction. A small pair of sails, or fans, M, are attached to the projecting framework, L L, of the back part of the cap; it has a pinion upon its axle, which engages in a wheel *b* attached to the inclined axis *cc*, and at the other end of this axle a bevelled pinion is fixed, which works in a wheel *e* on the vertical spindle of the pinion *f*; (see also fig. 4;) this latter pinion engages the cogs on the outside of the rim of the fixed curb, and by these means whenever the fan M is turned, it moves the head of the mill slowly round with a power depending upon the ratio of the radii, or number of teeth in the wheels and pinions above described. It will be readily seen by examining the manner in which the sails of the fan are constructed, that when its plane is in the direction of the wind it will not be put in motion by it, but if the wind varies in the least from the direction of the main shaft of the sails, it acts obliquely upon these vanes or sails of the fan, and turns them round in such a direction that, on whichever side the wind may come, the motion thus conveyed to the Machinery of the cap brings it again into the direction of the wind.

This ingenious contrivance is not a very recent invention; it is made use of in a great many cases, but is considered by some millwrights too slow in its action, as it is sometimes necessary in sudden gales, where there is danger of setting fire to the mill by using the brake, to turn the sails quickly out of the wind; whereas the action of the fan is constantly to bring it in. In this case, the self-acting cap is inconvenient and dangerous; but as these accidents happen but very rarely they ought not to be advanced as a serious objection to this contrivance, which, in other respects, has many advantages.

(99.) *Construction of the sails.*—The construction of the sails, and the method of fixing them to the wind shaft are operations which form the most important branch of mill making, and upon which materially depends the power and good effect of the mill. Cast-iron shafts,

Machinery

Self-adjust-
ing cap.

Construc-
tion of the
sails.

Manufac-
tures.

Fig. 5.

which are now almost universally made use of from the great advantages they possess over wooden ones, have two sockets or rectangular holes in their extremity, for the reception of the arms; and two pieces of timber, (*h h*, fig. 5.) of considerable length, termed the *horns*, are placed at the back of them, to which the arms are secured for several feet of their length by screw bolts and nuts. These horns serve not only to keep the arms steady in the sockets, but very materially to strengthen them, and as an additional security in large mills, braces are sometimes attached to near the end of the arms, and to a projected part of the wind shaft. In some instances cast-iron arms are left on the shaft to secure the whips in the sockets; this method is, however, neither so secure, or so frequently adopted as the former one.

Fig. 6.

Referring to fig. 6, *DEFG* is a section of the shaft perpendicular to the axis *C*. *HH*, *AB*, are the whips which are placed at right angles to each other; they are about 10 inches square, or 10 by 8, and 40 feet long, consisting of one piece of timber; it is, however, sometimes necessary to employ two pieces scarfed together, in which case strengthening pieces are attached, and from these the braces proceed to the projected shaft.

Fig. 7.

At a distance, *CL*, equal to one-seventh of the whip, the first bar, *LM*, is fixed; it is represented in the vertical projection of the sail, fig. 7, by the dotted line *oo'* which makes an angle of 60° with the axis of the wind shaft, and in the same figure the dotted line *oP* is the projection of the outermost bar *NB'*, which makes an angle with the same axis of 80° . The space *LN* is divided into an equal number of parts for the position of the intermediate bars, of which there are usually about twenty. These bars are mortised into the whip, and at the other extremity into the piece *MB'*, which extends the whole length of the sail and serves to secure their ends. It will be seen that each bar makes a different angle with the axis. In this case, the difference of the extreme angles being 20° , and there being twenty bars, the difference of angle in each successive bar is 1° .

All the bars are usually made of the same length, *viz.* about five feet, but in some mills the outermost is made to project about half its length on the other side of the whip, the intermediate ones being gradually diminished to the first bar which does not project; these are termed enlarged sails. In other mills the outermost bars are made of less length to imitate the wings of a bird; these, however, are not considered good.

The square sails now commonly adopted in this Country, are known by the term Dutch sails. They have been minutely described by Coulomb from an examination of more than fifty mills in the neighbourhood of Lisle.

These various Machines he found to perform the same quantity of work when the wind had a velocity of about 18 or 20 feet per second, though some differences existed in the inclination of their axles or wind shafts, and in the disposition of their sails; and from that circumstance Coulomb concluded that the parts of the Machine must have been constructed and disposed so as to produce nearly the maximum effect.

Dutch sails.

(100.) The length of the Dutch sails from their extremity to the centre of the wind shaft is about 33 feet; they

have a rectangular form, and are a little more than six feet wide, five feet of which are covered with the cloth, and the remaining one foot is thin board. The sail cloth commences six feet from the centre, and is, therefore, only 27 feet long. The line of junction of the board and cloth forms on the side which faces the wind a curve sensibly concave, at the commencement of the sail; but the curvature diminishes gradually till it vanishes at its extremity. The angles which the tangents to these curves form with the plane of their motion is called the *angle of weather*. This at the first bar is 30° , and gradually diminishes to 12° in some cases, and to 6° in others, varying within these limits accordingly as the inclination of the wind shaft varies from 8° to 15° .

We have above only considered the sails of wind-mills to consist of four arms; there are, however, some few instances in which five or more are made use of, but such cases are rare, and it will, therefore, not be necessary for us here to enter into a particular description of them.

(101.) *On the best shape and angle of inclination of the sail of wind-mills.*—This is a subject which has engaged the attention of several mathematical and scientific men, and among others the celebrated Smeaton, who, in two papers read before the Royal Society, described the result of a very complete and satisfactory set of experiments made with a view of correcting the anomalies in the results of the mathematical investigations of Parent and Maclaurin. A description of these experiments has been already given in the Essay on PNEUMATICS in this Work, to which, or to the *Philosophical Transactions*, vol. li., we beg to refer the reader for the detail; in the present instance it will be sufficient to give those only which more particularly bear upon the present subject.

The apparatus he made use of consisted of a vertical axle supported so as to be free to revolve in a proper framework, with a long horizontal arm attached to it, at the end of which were fixed four small movable sails. The vertical axle being set in motion by means of a weight attached to a rope wound round its circumference, the sails met with a constant and equable blast of air, and a string, with a scale for weights affixed to it, was attached to the axle of the sails, which served as a measure of their power to revolve, so that by this means a comparison of the powers of different shapes and angles was accurately made. In the following Table are given the results of nineteen sets of experiments on wind-mill sails of various structures, positions, and quantities of surface.

Several experiments were made for each description of sail to ascertain the maximum effect, *i. e.* the greatest product of the weight into the number of revolutions of the sails. In Table I., column 4 is the number of revolutions of the sails unloaded; column 5 the number which produced the maximum; column 6 the weight at the maximum; and column 8 the maximum or greatest product of weight multiplied into the number of turns. The other columns are sufficiently explained by the heads, and need no further remarks.

The velocity given to the centre of the sails in the circumference of their circle was six feet in a second.

In the following results a proper allowance is made for the friction of the pulleys and rigidity of the ropes, both of which were accurately ascertained by Mr. Smeaton.

Remarks on the above Table

(102.) Upon the results of these experiments Mr. Smeaton remarks :

1. That the sails set at the angle with the axis, proposed as the best by Parent and others, viz. 55°, were found to have the least effect of any that were tried.

2. That when the angle of the sails with the axis was increased from 55° to between 72° and 75°, the power or product was augmented in the proportion of 31 to 45.

3. That if nothing more were requisite than to cause the sails to acquire a certain degree of velocity by the wind, the position recommended by Parent would be the best ; but if the sails are intended with given dimensions to produce the greatest effect possible in a given time, we must, if plans are made use of, confine the angle within the limits of from 72° to 75°.

4. That the variation of a degree or two, when the angle is near the best, is but of little consequence, and that when the wind falls upon a concave surface, it is an advantage to the power of the whole, although every part taken separately would not be disposed to the best advantage.

5. That from several trials on a larger scale, he has found the following angles to answer as well as any. The radius is supposed to be divided in six parts, and one-sixth, reckoning from the centre, is called 1, the extremity being denoted 6.

Number.	Angle with the axis.	Angle with the plane of motion.
1	72°	18°.
2	71	19
3	72	18 middle.
4	74	16
5	77½	12½
6	83	7 extremity."

The author further remarks, that a broader sail re-

quires a larger angle, and that when the sail is broader at the extremity than near the centre, this shape is more advantageous than that of a parallelogram, and that the figure and proportion of the enlarged sails which he found best to answer on a large scale, were when the extreme bar was one-third of the radius or whip, and divided by the whip in the proportion of 3 to 5. In the latter case the triangular or leading sail was formed of board from the point downwards one-third of its height, the rest with cloth as usual.

Many have imagined that the more sail the greater the advantage, and have therefore proposed to fill up the whole area, and by making each sail a sector of an ellipsis, according to Parent, to intercept the whole cylinder of wind, and thereby to produce the greatest effect possible ; but from our author's experiments it appears that when the surface of all the sails exceeded seven-eighths of the area, the effect was rather diminished than augmented. Hence he concludes, that when the whole cylinder of wind is intercepted, it cannot produce the greatest effect for want of proper interstices to escape.

Mr. Smeaton states, that it is certainly desirable that the sails of wind-mills should be as short as possible ; but it is equally desirable that the quantity of cloth should be the least that may be, to avoid damage by sudden squalls of wind. The best structure therefore for large mills is when the quantity of cloth is the greatest that can be in a given circle : on this condition that the effects hold out in proportion to the quantity of cloth ; for otherwise the effect can be augmented in a given degree by a lesser increase of cloth upon a larger radius than would be required if the cloth were increased upon the same radius.

Manufactures.

The most useful figure therefore for practice is that of No. 9 or 10 in the Table, as has been experienced in several mills upon a large scale.

Mr. Smeaton having in the preceding experiments made a comparison of the power of different surfaces and angles of weather with the same velocity, next pro-

ceeded to determine the effect according to the different velocities of the wind. These experiments were made with the same apparatus as the former ones, and the sails were of the same kind as those of Nos. 10, 11, and 12 in the preceding Table.

Remarks on Table II.

(103.) The results of these experiments Mr. Smeaton enters into at considerable length. We shall, however, only give here the laws (or, as he terms them, maxims) which have resulted from his investigations and comparisons, again referring the reader who is desirous of examining the detail, to vol. li. of the *Philosophical Transactions*, or the *Abridgement*, vol. xi.

Maxim 1. The velocity of wind-mill sails whether unloaded or loaded, so as to produce a maximum, is nearly as the velocity of the wind, their shape and position being the same.

2. The load at the maximum is nearly, but somewhat less than, as the square of the velocity of the wind, the shape and position of the sails being the same.

3. The effects of the same sails at a maximum are nearly, but somewhat less than, as the cubes of the velocity of the wind.

4. The load of the same sail at a maximum is nearly as the squares, and their effect as the cubes of their number of turns in a given time.

5. When sails are loaded so as to produce a maximum at a given velocity, and the velocity of the wind increases in a slight degree, the load continuing the same, the increase of effect will be nearly as the squares of those velocities; but when the velocity of the wind is increased to double, the effects will be nearly as 10 to 27½; and when the velocities compared are more than double of that where the given load produces a maximum, the effects increase nearly in the simple ratio of the velocity of the wind. Hence he concludes that wind-mills of the different descriptions, for raising water, drainage, &c., lose much of their effect when acting against one invariable opposition.

6. In sails of a similar figure and position the number of turns in a given time will be reciprocally as the radius or length of the sail.

7. The load at a maximum that sails of a similar figure and position will overcome at a given distance from the centre of motion will be as the cube of the radius.

8. The effects of sails of similar position and figure

are as the square of the radius. Hence it follows that augmenting the length of the sail, without augmenting the quantity of cloth, does not increase the power: because what is gained by the length of the lever is lost by the slowness of motion. Hence, also, if sails are increased in length, the breadth being the same, the effect will be as the radius.

9. The enlarged sails are superior to those of the common Dutch construction, which, Mr. Smeaton further remarks, perfectly agrees with the practical observations he has had opportunities of making on this subject.

10. The velocity of the extremities of the common Dutch sails as well as of the enlarged sails, either when unloaded, or even when loaded, to a maximum, is considerably greater than that of the wind itself.

Mr. Smeaton in this way made out a Table of the velocities of the wind according to their common appellations, by ascertaining the exact ratio of the extremity of the particular sail he observed with the velocity of the wind; this has been already given in our Essay on PNEUMATICS.

(104.) *Clothing the sails.*—In the above experiments the sails have in each case been full set; it is, however, necessary, when the wind is very high, to take in a part of the cloth, and there are usually four states in which it can be set according to the velocity of the wind and quantity of work to be performed, which are termed *full sail*, *quarter reef*, *sword point*, and *dagger point*. The mode of effecting this is by ropes fastened to the sail at the three points *a b c*, (pl. vi. fig. 6,) which pass either through rings, or over the ends of the bars which project beyond the piece *M B'*, and by releasing these lines the sails may be very readily reefed up to any of the positions shown by the dotted lines in the figure.

It is, of course, necessary when the quantity of sail is varied that the mill should be stopped, an operation which is often attended with a great deal of inconvenience and loss of time. Those who occupy mills well know the danger they are often exposed to from sudden squalls of wind and hard gales continuing and increasing while the sails are clothed and going, which are often

Clothing the sails.

Manufac-
tures.

incapable of outriding the storm. The shafts, if not wrung off at their necks by the too frequent application of the brake, are so crippled and weakened as to be rendered unfit to be trusted, after repeated injuries of this kind, and various accidents arise in consequence, often attended with loss of life. In addition to this the uncertainty of the wind and danger in long and dark nights, often deter the miller from grinding when he is in the greatest need, and the time and trouble necessary to stop the mill and alter the cloth so frequently in unsettled weather, are such as to disable him from doing a great proportion of the work which could otherwise be done at those times.

These various inconveniences attending the common mode of clothing sails have led to several inventions, to enable the miller to clothe the sails in an expeditious manner, while they are in motion, and several patents have been taken out for different modes of accomplishing this purpose, of which the three following have been most approved and adopted.

Self-adjust-
ing sails.

Mickle's
method.

(105.) *Self-adjusting Sails.*—One of the first attempts at accomplishing this object was by Mr. Andrew Mickle, the inventor of the threshing-machine, in 1772. The length of the sail is here divided into eleven compartments, by the bars forming a number of oblong openings, which are each filled up by a square frame of wood covered with canvass, and mounted on pivots at their ends, one pivot turning in a hole in the whip, and the other in the bar which lies parallel to it, in the manner of a Venetian blind; the pivots are not placed in the middle of the breadth of the frames, but at one-third from the edge, towards the shaft or axle of the sails. On the end of each pivot which enters the whip, a small roller is fixed, round which a chain passes, and its end is attached to a steel spring, placed at right angles to the whip, and in the direction of the length of the canvassed frames. Now if the wind blows too hard it acts to turn the frames edgewise, in which case the wind passes through the sails, and exerts less force to turn them round, but as soon as the wind becomes moderate, the steel spring brings up the frames into a plane presenting their whole surface to its action. A rod of iron extends the whole length of the whip, and is connected with several springs, to afford the means of strengthening or diminishing their action according to the season of the year. This rod is formed with a screw and nut at its outer extremity to enable the miller to adjust the strength of the springs conveniently, from the circular gallery surrounding the outside of the mill.

Bywater's
patent.

Plate viii.
fig. 7, 8.

(106.) Mr. John Bywater of Nottingham took out a patent in 1804 for a method of clothing and unclothing the sails of wind-mills while in motion; which consisted in rolling or folding them up to the whip by means of cylinders or rollers, which extended the whole length of the sails, and were put in motion when required by a system of wheel-work connected with the shaft in the following manner. A ring of iron, *a*, pl. viii. fig. 7, about four inches wide, and three-quarters of an inch thick, is attached to the main shaft (and concentric with it) a short distance behind the whip. A bevelled wheel, *b*, without arms, is made so as to revolve easily upon the circumference of the ring, and a spur wheel without arms is made to turn upon four pins or ears in the back of the ring. The arrangement of this part will be better understood from fig 8, which is a back view of the ring of iron; *c* is the spur wheel which turns upon the pins; *d d d d* and *e e e e* are four pinions, which are

attached to a spindle, having at their other extremity bevelled pinions, *f f f f*, fig. 7, which work in similar ones attached to the rollers, *P P*. Upon these cylinders the sails are rolled up; they are about three inches diameter, made of wood, one being placed at the outside of the leading edge of each sail. A gudgeon from the end of each cylinder turns in an iron fastened to the shaft head, and is kept in its place by a nut screwed to the end. The other end has a gudgeon, which turns in the eye of the cross iron, *g g*, fixed on the end of the whips. Four cylinders, one of which is shown at *R* in the figure, similar to *P P*, are placed on the inside of the whips, which have ropes round their circumferences, and fastened to the edges of the cloth of the sail, so that by the revolution of this cylinder the sail is clothed. The cylinder has a bearing at one end in the cross iron, at the end of the whip, and at the other, either in a projecting part of the iron rim, or in the shaft-head; it has a small bevelled wheel, *h*, which works in the bevelled wheel *b*, upon the iron ring, by means of which motion is conveyed to it.

The Machinery in the ordinary state of the mill revolves with the shaft undisturbed, and is only put in action when any variation of the quantity of cloth is required, which is done in the following manner. Suppose the mill fully clothed, and that it is required to diminish the quantity of canvass; a lever, which is fastened to the bracing or fencings, and which is weighted so as to hang vertically, is brought into a horizontal position by means of a string attached to the end within the mill. In this position it engages a stud, *s*, upon the spur wheel, and prevents its motion. The bevelled wheel, *b*, and iron rim of course continue to revolve with the shaft, and, consequently, give motion to the small pinions, and with them the cylinder *PP* which will continue to wind up the cloth until the end of the lever is disengaged from the stud, which at once stops the action of the Machinery, so that the miller, by letting go the string, can at any time leave the cloth on the sail where he chooses. In a similar manner, when it is necessary to clothe the sails, a lever is made to engage a stud, *t*, upon the bevelled wheel, and, by stopping it, to give motion to the bevelled pinion and cylinder, *R* which winds up the ropes and draws the cloth gently forward upon the bar. In this way the miller has the action of the Machinery completely at command, so that by pulling one or the other string he may adjust the quantity of sail exactly to the strength of the wind and nature of the work the mill has to perform.

In order to prevent the springing of the cylinders, which they are liable to when of great length, a stay of wood is fixed at *n*, having in the inside room enough to allow the cloth to be rolled up. As the cords, *o o o*, &c., which go over to the edge of the shrouds, are liable to get loose in dry weather, a cord passing over a spring of any sort or shape placed under the sail, is fastened to and wound about the upper ends of the cylinders in a direction contrary to the strings and cloth, this, by making every thing tight, renders the action of the Machinery more steady and instantaneous.

Mr. Bywater also mentions, in the specification of his patent, a mode of folding up the cloths instead of rolling them up, by means of which he does away with one set of rollers. The manner of effecting it he thus describes:—"One end of the cloth must be fastened to the whip, and lines passed across the outside of it through loops fastened to its edge, and continued over the edge of the

Machinery.

Manufactures. shrouds, and connected with a cylinder or roller of any shape placed under the sail or elsewhere; the other ends of the lines must also be connected with the said cylinder or roller; and when the cloth is drawn up in folds towards the whip, so much of these lines will be rolled on the cylinder one way, and off from it on the other, as will be sufficient to let out the cloth again when the same cylinder, turned the contrary way, draws the cloth on the sail. By this mode four cylinders with their appendages are avoided, the works being in other respects the same as in rolling the cloths; but since folding gives a surface much inferior in many respects to rolling, and leads to inconveniences and accidents from which the rolled surface is free, the inventor advises the rolling, rather than from a small saving to incur the inconveniences of folding.

This method of clothing wind-mill sails possesses considerable advantages over the common mode, not only in avoiding the loss of time and frequent danger attending it, but they will afford the miller more power than prudence would allow him to adopt, without the constant and ready control which by this Machinery he will always be able to exercise over the wind.

Cubit's patent sails. (107.) Mr. William Cubit, Civil Engineer, took out a patent in the year 1807, for a method of equalizing the motion of the sails of wind-mills, which, in some measure, resembles that of Mr. Mickle, the sails being composed of a series of vanes or valves suspended at their ends by pivots in the framework of the sails; and these vanes are contrived to present a greater or less surface to the wind, according as it acts with more or less force upon them. If the wind be very strong, the vanes by its impulse turn their edges to it, and their surfaces parallel to the direction of the wind, and would, consequently, remain stationary, or, at least, have but little motion. To obviate this inconvenience, he employs an apparatus which causes the vanes to present their flat surfaces to the wind, or such portion of their surfaces as may be desirable.

Fig. 9. Fig. 9 represents a set of vanes in which A A show the valves turned to the wind, and their surfaces exposed at right angles to it. B B exhibits the vanes as close reefed, with their edges to the wind, so that it can have no effect upon them, except on their edges. In the drawing, the vanes are exhibited as having the whip down the middle, with valves on both sides; but it is evident that the vanes may be constructed with the whip placed in the usual way, and have valves on one side only.

Fig. 10. Fig. 10 is a section through the wind shaft, exhibiting the apparatus for regulating the vanes. A is the wind shaft, which is bored through its centre to admit an iron rod, B, to pass freely through it; one end of this rod has a knol or onion on it, which turns in a box, c, so that it can be moved endwise, while it continues to revolve. The box c is fastened to a toothed rack, D, whose teeth engage those of a pinion, E, upon the spindle of which is a sheave, F, with a groove on its circumference to receive a rope, G, to which is hung the weight W. This weight serves to regulate the force of the wind upon the valves, and may be adjusted to the nature of the work to be performed by the mill. On the other end of the rod is fixed a plate of iron, K, with ears upon it, projecting from each side, in which are fixed the bridles or leaders, L L, which permit the levers M M to describe a curve with their ends, while the iron rod B moves in a straight line. N N are two uprights or props, on the ends of which the levers M M

VOL. VII.

move, and communicate the motion of the iron rod B Machinery. to the racks P P. These racks engage the pinions Q Q, on the axis of which (according to one method here described, fig. 10.) is fixed a strong iron lever or crank Fig. 10. c; the end of this is attached to a slider S. Each vane has a small lever projecting from it, which is fixed in the slider by a pin or gudgeon, so that by the motion of the slider the vanes present a different angle to the wind.

The other method of regulating the vanes is shown Fig. 11. in fig. 11, where, instead of levers, the vanes have a pinion attached to them, which engages the teeth of a rack or slider T.

The operation of this apparatus will be readily understood by imagining the rope G pulled down so as to cause about three-quarters of a revolution of the sheave F. The pinion E will put in motion the rack D and rod B, which brings the levers into the position represented by the dotted lines: the rack P P will have turned the pinions till the sliders S or T (according to whichever method may be used) bring the vanes into such a position that their whole surface is presented to the wind; therefore, if a weight be hung upon the line G, it will keep the surface of the vanes to the wind, until the strength of it is such as to raise the weight, when the vanes will be more or less opened until the pressure upon the inclined surface is reduced so as to balance the weight; by this means the force of the wind beyond that sufficient to raise the weight, will not produce any additional velocity, and a degree of regularity will be attained which can never be produced by the ordinary method.

Several other methods of equalizing the sails of wind-mills have been invented; but those above described are the only ones we are aware of which have been brought into practice, and these, although allowed by millers to possess considerable advantage over the common mode, are, probably from their additional expense, not brought by any means into general use.

(108.) *Horizontal wind-mills.*—In consequence of the Horizontal wind-mills. very small angle at which the sail of the vertical wind-mill is inclined to the direction of its motion, which at a medium cannot be estimated at more than 20° , and of which angle, the sine which represents the force, to give motion to the sails, scarcely exceeds one-third of the radius, much of the power of the wind is necessarily lost; and hence have arisen endeavours to substitute horizontal for vertical sails, under a mistaken idea that more power would be acquired by the former than by the latter. Some constructions of this kind have been carried into effect, and are, we believe, still at work, or were very recently, one at Battersea, and one at Margate. As they are, however, now by universal consent admitted to be inferior to the vertical ones, it would be uselessly filling our pages, and unpromptly engaging the attention of the reader to enter into a description of them. We therefore beg to refer those who may be desirous of obtaining information on this subject to the *Theatrum* of the celebrated Leopold, and the *Repertory of Arts*, in each of which will be found a great number of contrivances for this purpose.

(109.) Mr. Smeaton, in his paper to the Royal Society on the power of wind to turn mills, which we have before mentioned, enters into the following investigation, in which he proves in a very satisfactory manner the cause of the disadvantages attending this mode of applying the power of wind. He remarks in the commencement of his

T

Manufac-
tures.
Smeaton's
remarks on
horizontal
wind-mills.

paper that "observations upon the effects of common wind-mills with oblique vanes, have led many to imagine that could the vanes be brought to receive the direct impulse, like a ship sailing before the wind, it would be a very great improvement in point of power; while others attending to the extraordinary effects of oblique vanes, have been led to imagine that oblique vanes applied to water-mills would as much exceed the common water-wheels, as the vertical wind-mills are found to have exceeded all attempts towards an horizontal one. Both these notions, but especially the first, have so plausible an appearance, that of late years there has seldom been wanting those who have assiduously employed themselves to bring to bear designs of this kind; it may not, therefore, be unacceptable to endeavour to set this matter in a clear light."

Fig. 12.

Let AB , fig. 12, be the section of a plane, upon which the wind blows in the direction CD , with such a velocity as to describe a given space BE , in a given time, (suppose one second,) and let AB be moved parallel to itself, in the direction CD . Now if the plane AB moves with the same velocity as the wind; that is, if the point B moves through the space BE in the same time that a particle of air would move through the same space; it is plain that, in this case, there can be no pressure or impulse of the wind upon the plane; but if the plane moves slower than the wind, in the same direction, so that the point B may move to F , while a particle of air, setting out from B at the same instant, would move to E , then BF will express the velocity of the plane; and the relative velocity of the wind and plane will be expressed by the line FE . Let the ratio of FE to BE be given; (suppose $2:3$;) let the line AB represent the impulse of the wind upon the plane AB when acting with its whole velocity BE ; but, when acting with its relative velocity FE , let its impulse be denoted by some aliquot part of AB , as for instance $\frac{2}{3}AB$; then will $\frac{2}{3}$ of the parallelogram AF represent the mechanical power of the plane; that is, $\frac{2}{3}AB \times \frac{1}{3}BE$.

Fig. 13.

Secondly, let IN , fig. 13, be the section of a plane, inclined in such a manner that the base IK of the right angled triangle IKN may be equal to AB , and the perpendicular $NK = BE$; let the plane IN be struck by the wind, in the direction LM , perpendicular to IK , then, according to the known rule of oblique forces, the impulse of the wind upon the plane IN , tending to move it according to the direction LM or NK , will be denoted by the base IK ; and that part of the impulse tending to move it according to the direction IK , will be expressed by the perpendicular NK . Let the plane IN be movable in the direction of IK only; that is, the point I in the direction IK , and the point N in the direction NQ parallel thereto. Now it is evident that if the point I moves through the line IK , while a particle of air, setting forward at the same time from the point N , moves through the line NK , they will both arrive at the point K at the same time; and, consequently, in this case also, there can be no pressure or impulse of the particles of air upon the plane IN . Now let IO be to IK as BF to BE ; and let the plane IN move at such a rate, that the point I may arrive at O , and acquire the position OQ at the same time that a particle of wind would move through the space NK : as OQ is parallel to IN , (by the properties of similar triangles,) it will cut NK in the point P , in such a manner, that $NP = BF$ and $PK = FE$; hence it appears, that the plane IN by acquiring the position OQ , withdraws

itself from the action of the wind, by the same space NP , Machinery. that the plane AB does by acquiring the position FG ; and, consequently, from the equality of PK to FE , the relative impulse of the wind PK upon the plane OQ , will be equal to the relative impulse of the wind FE upon the plane FG ; and since the impulse of the wind upon AB with the relative velocity FE , the direction BE is represented by $\frac{2}{3}AB$; the relative impulse of the wind upon the plane IN , in the direction NK , will in like manner be represented by $\frac{2}{3}IK$; and the impulse of the wind upon the plane IN , with the relative velocity PK , in the direction IK , will be represented by $\frac{2}{3}NK$; and consequently the mechanical power of the plane IN , in the direction IK , will be $\frac{2}{3}$ of the parallelogram IQ ; that is $\frac{2}{3}IK \times \frac{1}{3}NK$; that is, from the equality of $IK = AB$ and $NK = BE$ we shall have $\frac{2}{3}IQ = \frac{2}{3}AB \times \frac{1}{3}BE = \frac{2}{3}AB \times \frac{1}{3}BE = \frac{2}{3}$ of the area of the parallelogram AF . Hence we deduce this general proposition, *That all planes, however situated, that intercept the same section of the wind and having the same relative velocity, in regard to the wind, when reduced into the same direction, have equal powers to produce mechanical effects.*

For what is lost by the obliquity of the impulse is gained by the velocity of the motion.

Hence it appears, that an oblique sail is under no disadvantage in respect of power, compared with a direct one, except what arises from a diminution of its breadth in respect to the section of the wind, the breadth IN being obliquely reduced to IK .

The disadvantage of horizontal wind-mills, therefore, does not consist in this; that each sail, when directly exposed to the wind, is capable of a less power than an oblique one of the same dimensions, but that in a horizontal wind-mill, little more than one sail can be acting at once; whereas in the common wind-mill, all the four act together; and, therefore, supposing each vane of a horizontal wind-mill of the same dimensions as each vane of the vertical, it is manifest the power of a vertical mill with four sails, will be four times greater than the power of the horizontal one, let its number of vanes be what it will. This disadvantage arises from the nature of the thing; but if we consider the further disadvantage that arises from the difficulty of getting the sails back again against the wind, &c., we need not wonder if this kind of mill is in reality found to have not above $\frac{1}{8}$ or $\frac{1}{10}$ of the power of the common sort, as has appeared in some attempts of this kind.

(110.) *Water-mills.*—It has been already explained Water-mills. that by the term water-mill, as applied in this Chapter, is only to be understood that part of the general Machine employed in producing a first rotation, without any reference to the Machinery intended to be driven by it. We have only here, therefore, to speak of the wheels, and show their construction, and the advantages or disadvantages of their different forms and modes of action.

We have already, under the article in which water is treated of as a first mover, defined the different kinds of water wheels, which, as far as the figure and construction is concerned, may be reduced to two or at most to three. The balance and overshot wheel being precisely the same in form, and the undershot and breast wheel differing only in the one being an open wheel with floats, while the other is close soled, and sometimes close shrouded; that is, it is close boarded on its circumference which is called the soling, and sometimes also closed in on its sides to the depth of the floats which is called the shrouding.

Manufac-
tures.

Water wheels were formerly, and are still occasionally, made of wood; but they are now more commonly made of iron. When overshot wheels are made of this material, two iron wheels are first cast whole or framed after the manner already described for fly wheels, &c.; and to the extremity of their arms, or to their rims, the shrouding is bolted and screwed. These wheels being fixed on an axle at a proper distance from each other, the parts forming the soling and buckets are also bolted and screwed between them to flanches formed for the purpose, by which the whole becomes one wheel.

Pl. vii.
Fig. 1.

The form of the buckets is considered a matter of considerable importance: an idea of their shape and arrangement may be formed by the dotted lines in fig. 1; but a more particular description of their figure and construction is given below.

A slight consideration of the nature and action of the overshot wheel is sufficient to convince the reader of the impossibility of constructing the buckets so as to remain completely filled with water till they reach the bottom of the wheel; indeed, if the buckets were formed by partitions directed to the axis of the wheel, the whole water must run out by the time they had descended to the level of the axis, and of course there would be a great diminution in the mechanical effect. Millwrights have therefore turned their attention to finding the best figure to be given to the partitions forming the buckets; that is, to the finding such form as shall enable them to retain their water as long as it is useful and no longer, in their descent towards the lower part of the wheel. We say as long as it is useful; for it is plain, if it could be retained to the bottom, as it could not then immediately escape, a part of it would be carried up and would of course counteract the effect of the descending water. It would occupy considerable space to attempt to describe here one half of the numerous contrivances which have been recommended with a view of accomplishing this object, we shall therefore content ourselves with describing one or two only of those which are esteemed the best.

Construc-
tion of the
buckets of
water
wheels.
Fig. 3.

(111.) *Construction of the buckets.*—In fig. 3, A M represents the part of the shrouding or ring of buckets of an overshot wheel of forty buckets. The form of one of these is shown by G O F A B C D; in which the sole of one bucket A F should be $\frac{2}{3}$ of A E, the depth of the shrouding, and the shoulder A B of the bucket should be one half of A E. The arm B C of the bucket must be so inclined to the shoulder A B that H C perpendicular to A H F at H may be $\frac{2}{3}$ of A E; and the wrist of the bucket C D must be so inclined to B C n, the direction of the arm, that D n may be $\frac{1}{3}$ of E n.

From this construction it follows that the area H A B C is very nearly equal to D A B C; so that the water which will fill the space H A B C will all be contained in the bucket when it comes into such a position that A D is a horizontal line; and the line A B will then make an angle of 35° with the vertical, or the bucket will be 35° from the perpendicular passing through the axis of motion. If the bucket descend so much lower, that one-half of the water runs out, the line A B will make an angle of about $24\frac{1}{2}^\circ$ with the vertical. Therefore the wheel filled to the degree now mentioned, will begin to lose water at about $\frac{1}{8}$ of the diameter from the bottom, and half of the water will be discharged from the lowest bucket about $\frac{1}{2}\frac{1}{4}$ of the diameter further down. Had a greater proportion of the buckets been filled with water when they were under the spout, the discharge would have begun at a greater height from the bottom, and a

greater portion of the whole fall of water would be lost. Machinery. The loss by the preceding construction is less than $\frac{1}{10}$, supposing the water to be delivered into the wheel quite at the top, and may be estimated at about $\frac{1}{12}$; for the loss is as the versed sine of the angle which the radius of the bucket makes with the vertical.

The versed sine of 25° is 0.18085, or nearly $\frac{1}{5}$ of the radius, or $\frac{1}{10}$ of the diameter. Had only $\frac{1}{2}$ of this water been supplied to each bucket as it passed the spout, it would have been retained for 10° more of a revolution, and the loss of fall would have only been about $\frac{1}{18}$.

(112.) *Another method.*—Other millwrights divide the bucket by a partition, concentric with the sole and rim, and of such an altitude, as to make the inner and outer portions of the bucket of nearly equal capacity. In consequence of this contrivance, the fluid is longer retained in the descending buckets; and when the supply of water is very scanty, a proper adjustment of the apparatus which regulates the position of the spout will direct nearly all the water into the exterior buckets, and thus, by placing it at a greater distance from the axis, sensibly augment its mechanical energy. Dr. Robison, in speaking of this construction, suggests also that the breadth of the buckets, or the rim of the wheel, should be tolerably large, that the quantity of water received from the spout may not nearly fill the buckets. And in order to prevent the air from impeding the rising buckets, or, as the millers term it, the buckets from sucking up the tail water, he advises that the shoulder or strut of each bucket be perforated with a few holes. As to the spout which conveys the water, it should be considerably narrower than the breadth of the wheel; and the distance of the spout from the receiving bucket should also in general be two, three, or four inches, that the water may be delivered with a velocity a little exceeding that of the rim of the wheel, otherwise the wheel will be retarded by the impulse of the buckets against the stream, and the dashing of the water over would occasion a diminution of power.

With respect to variations in the fall of water, since the active pressure is measured by the pillar of water reaching from the horizontal plane where it is delivered on the wheel, to the horizontal plane where it is spilled by the wheel, it has been concluded, that the pressure must be proportional to the wheel; and, therefore, the water must be delivered as high, and retained as long as possible. This maxim, however, is subject to limitations, and is not perhaps consistent with sound theory. When the fall is exceedingly great, a wheel of an equal diameter becomes enormously big, and extremely expensive. In cases like this, where we are unwilling to lose any part of the force of a full stream, the best form of a bucket wheel is an inverted chain pump, or *chain of buckets*. Gregory, *Mechanics*, vol. ii.

(113.) *Of the velocity of an overshot wheel.*—This is a matter calling for great care and attention; different authors having arrived at very opposite conclusions respecting it. Theory seems to indicate that an overshot wheel does the more work, as it moves slower. The popular reasoning adduced to prove this has been of the following kind. Suppose that a certain wheel has thirty buckets, and that six cubic feet of water are delivered in a second on the top of the wheel, and discharged without any loss by the way, at a certain height from the bottom. Let this be the case, whatever is the rate of the wheel's motion, the buckets being of a sufficient capacity to hold all the water which falls into them. Suppose this wheel

Velocity of
overshot
water
wheels.

Manufac-
tures.

employed to raise a weight of any kind, water, for instance, in a chain of thirty buckets, to the same altitude and with the same velocity. Suppose, further, that when the load on the rising side of the Machine is one half of that on the wheel, the wheel makes four revolutions in a minute, or one turn in fifteen seconds. During this time, 90 cubic feet of water will have flowed into the thirty buckets, and each have received three cubic feet. In that case, each of the rising buckets contains one and a half feet; and 45 cubic feet are delivered into the upper cistern during one turn of the wheel, or 180 cubic feet in one minute.

Now, suppose the Machine so loaded, by making the rising buckets more capacious, that it makes only two turns in a minute, or one turn in thirty seconds. Then each descending bucket must contain six cubic feet of water. If each bucket of the rising side contain three cubic feet, the motion of the Machine would be the same as before. Our Machine would, therefore, continue to make four turns in a minute, and would deliver 90 cubic feet during each turn, or 360 in a minute. But, by supposition, it is making only two turns in a minute, which *must* proceed from a greater load than three cubic feet of rising water in each rising bucket. The Machine must, therefore, be raising *more* than 90 feet of water during one turn of the wheel, and *more* than 180 in a minute. Thus it appears, that if the Machine is turning twice as slow as before, there is more than twice the former quantity in the rising buckets; and more will be raised in a minute by the same expenditure of power. In like manner, if the Machine go three times as slow, there must be more than three times the former quantity in the rising buckets, and more work will be done.

These remarks are sufficient to show, in general, the advantage of slow motion; but they do not, it must be acknowledged, point out in any degree the relation between the rate of motion and the work performed, nor even the principle on which it depends. It is, however, sufficiently obvious, that there is not in the nature of things a maximum of performance attached to any particular rate of motion. All, therefore, we have to do is to load the Machine, and thus to diminish its speed till other physical circumstances interpose, and these will necessarily occur. In the action of a wheel and pinion, though made with the greatest judgment and care, inequalities cannot be avoided; and these increase by the change of form occasioned by wear, and all irregularity of this kind is more sensibly felt in slow motions and with great weights, than with greater velocities and less weights, and thus practical defects step in and prevent us here, as in other cases to which we have already referred, from pursuing advantages on one hand without introducing disadvantages on the other. The great question is, therefore, to determine the point where the maximum effect is produced; and as this depends so much on circumstances, it can be only determined when these circumstances are known, and then only by the experienced millwright. All calculations on such subjects are vain and useless. The following remarks, however, from Gray's *Treatise on Practical Mill-Work*, may be quoted with advantage.

Maximum
load of
overshot
wheels.

(114.) *Of the maximum load.*—The maximum load for an overshot wheel is that which reduces the circumference of the wheel to its proper velocity; which is known by dividing the effect it ought to produce in a given time by the space intended to be described by the circum-

ference of the wheel in the same time, and is equal to the load required, including the friction and resistance of the Machinery.

The greatest velocity that an overshot wheel is capable of, depends jointly upon the diameter or height of the wheel and the velocity of falling bodies; for it is plain that the velocity of the circumference can never be greater than to describe a semicircumference, while a body let fall from the top describes the diameter, nor even quite so great, as the difference in point of time must always be in favour of the diameter. Thus supposing the diameter of the wheel to be 16 feet one inch, a heavy body would fall through this space in one second; but such a wheel could never arrive at this velocity, or make one turn in two seconds, nor could an overshot wheel ever come near it; because, after it has acquired a certain velocity, great part of the water is prevented from entering the bucket, and part is thrown out again by the centrifugal force. In theory we may suppose a wheel to be made capable of overcoming any resistance whatever; yet as, in practice, it is necessary to make the wheel and buckets of some certain and determinate size, we always find that the wheel will be stopped by such a weight as is equal to the effort of the water in all the buckets of a semicircumference put together. This may be determined from the structure of the buckets themselves: but, in practice, an overshot wheel becomes unserviceable long before this time, for when it meets with such an obstacle as diminishes its velocity to a certain degree, its motion becomes irregular; but this never happens till the velocity of the circumference is less than two feet in a second, when the resistance is equable.

From the above observations we may easily deduce the force of water upon breast wheels, &c. But, in general, all kinds of wheels, where the water cannot descend through a given space unless the wheel moves with it, are to be considered as balance or overshot wheels; and those which receive the impulse or shock of the water, whether in an horizontal, oblique, or perpendicular direction, are to be considered as undershot. Hence a wheel on which the water strikes at a certain point below the surface of the head, and after that descends in the arch of a circle, pressing by its gravity upon the wheel, the effect of such a wheel will be equal to that of an undershot, whose head is equal to the difference of level between the surface of the water in the reservoir and the point where it strikes the wheels, added to that of an overshot, whose height is equal to the difference of level between the point where it strikes the wheel and the level of the tail water.

(115.) *Undershot wheels.*—Under this head are included such wheels as are impelled by the motion of the water independently of its weight, the theory of which has given rise to a great variety of opinions, discussions, and experiments. De Parcieu and Bossut have examined the best angle for the float boards to be fixed at, with respect to the radius of the wheel, in order to produce the best effect; and both agree in stating that a sensible advantage is gained by inclining them to the radius of the wheel at about an angle of 20° ; so that each float when lowest shall not be vertical, but be inclined towards the stream at the above angle. Such inclination, it is said, causes the water to accumulate along the float boards so as in some degree to act by its weight, and it is for this reason recommended that the floats should be made broader than the vein of water

Machinery.

Manufactures. interrupted by them is deep. This inclined float is now frequently but not generally adopted, and upon the whole, perhaps, the advantages attending it are not so great as were supposed by its first projectors.

Construction. *Construction of undershot wheels.*—These wheels, like the overshot wheels, are now generally made of iron, except the floats which are commonly of wood. Two iron wheels in this case, as in the former, are first cast or framed together, and at equal distances along their rims mortises are formed through, into which are securely fixed strong pieces of elm called *starts*. Now the two wheels being fixed on their axles at the proper distance, the floats are fixed across to these starts by proper bolts and nuts, the floats being commonly left projecting beyond the breadth of the wheel about one-eighth of their whole length on each side. See fig. 6.

Fig. 6. The breast wheel differs from this in its construction, only in being close soled and shrouded, as already explained, and of course, in this case, the floats have no projections.

Effect. (116.) *On the effect of undershot wheels.*—The great question relative to the best effect of undershot wheels, has always been the ratio that ought to subsist between the velocity of the wheel and that of the water; and in the *Treatise on HYDRODYNAMICS* in the preceding parts of this Work, Mr. Smeaton's experiments on this subject have been given at considerable length; it is only, therefore, for the sake of avoiding the inconvenience of frequent reference, that we give the following analysis of those results in this place, but for the more minute detail of them the reader must consult the Article in question.

First, it may be observed, that in order to compute the effects of water wheels, it is necessary to know what is the real velocity of the water that impinges on the wheel, the quantity expended in a given time, and what quantity of power is lost by the friction of the Machinery. This may be done as follows: to ascertain the force of any moderate stream of water, let it be obstructed by a dyke or dam across the stream, so as to force all the water through a trough or open spout into a square vessel or reservoir; measuring the quantity of water that runs into this reservoir in any given time, as for example, a second or minute. Multiply this quantity by the number of seconds or minutes in an hour, thus the whole impulse of such stream of waters at any given height, and of a medium breadth, may be readily ascertained. In rivers that are too large to be measured in this way, the force or impulse may be calculated thus: Let a narrow oblong square cistern, or reservoir, be fastened in the river with one end of it directed to the stream, having its upper edge a little above the surface, that no water can get into it over the top. In the end of this cistern, facing the stream of the river, is to be fixed a long spout of wood open above the upper edges of it, being level with the surface of the river, and at the same declivity with the current. Then the water will have the same velocity within the spout as the river on its outside; therefore by measuring the quantity of water that runs into the reservoir through the spout in a given time, suppose a minute, and multiplying the same by the minutes in an hour, the whole force or impulse of the river at any given height and known breadth may be ascertained.

Mr. Smeaton has also given tables of the velocities of a wheel with different heights of water; and from the whole deduces the following conclusions:

1. The virtual or effective head, that is head due to Machinery the velocity being the same, the effect will be nearly as the quantity of water expended.

2. The expense of water being the same, the effect will be nearly as the height of the virtual or effective head.

3. The quantity of water expended being the same, the effect will be nearly as the square of the velocity.

4. The aperture being the same, the effect will be nearly as the cube of the velocity of the water. Hence if the water passes out of an aperture in the same section, but with different velocities, the expense will be proportional to the velocity; and therefore if the expense be not proportional to the velocity, the section of the water is not the same.

5. The virtual head, or that from which we are to calculate the effect, however, bears no proportion to the head of water, but when the aperture is larger, or the velocity of the water less, they approach nearer to a coincidence, and consequently in the large openings of mill sluices, where great quantities of water are discharged from moderate heads, the head of water, and virtual head, determined from the velocity, will nearly agree; which is also confirmed by experience.

6. The most general proportion betwixt the power and the effect is that of 10 to 3; the extremes being 10 to 3.2, and 10 to 2.8. But it is observable, that where the power is greatest, the second term of the ratio is greatest also. Hence we may allow the proportion subsisting in great works to be 3 to 1.

7. The proportion of velocity between the water and the wheel is in general about 5 to 2.

8. There is no certain ratio between the load that a wheel will carry at its maximum, and what will totally stop it, though the proportions are contained within the limits of 20 to 10 and 20 to 15; but as the effect approaches nearest to the ratio of 20 to 15, or of 4 to 3, when the power is greatest, either by increase of velocity or quantity of water, this seems to be the most applicable to large works. But as the load that a wheel ought to have in order to work to the best advantage, can be assigned by knowing the effect that it ought to produce, and the velocity it ought to have in producing it, the exact knowledge of the greatest load is not a matter of much practical importance.

(117.) *Description of the figures.*—Pl. vii. figs. 1, 2, are Pl. vii. a front and side elevation of an iron overshot wheel; in Figs. 1, 2, 3, fig. 1, *pp* is the *pentrough* for conducting on the water; 4, 5, &c. *s* the *shuttle* for regulating the supply, which is drawn backward or forward by the lever *l* and the screw *m*. In fig. 2, *bb* is the principal bevel wheel which drives the Machinery; fig. 3 shows the section of the buckets enlarged and constructed according to the description. (Art. 106.)

Fig. 4 and 5 are the plan and elevation of an iron breast wheel, showing the *sluice s*, which works in grooves in the wall, and is elevated or depressed by means of a ratchet and pinion *r* and *p*, which is turned by the handle *h*, seen in fig. 4, and works inside the mill. In the same figure is seen the principal spur wheel *ww*, which drives the Machinery.

Fig. 6 and 7 are the elevation and plan of an undershot wheel, constructed according to a plan recommended by Smeaton. *s, s* is the sluice, or penstock, which is raised and depressed by the ratchet and pinion *r, p*; in fig. 7 is seen the principal spur wheel *ww*, resting on its bearings *b*.

We have in the above article confined ourselves

Manufac-
tures.

to a description of such water wheels as are in more general use; other forms, however, have been proposed, and partially adopted, one or two of which it may be well to refer to. Of these we have one (an undershot wheel) described in the *Transactions of the Society of Arts*, vol. xix., by Mr. Besant of Brompton; and in 1819 a patent was granted to Mr. Lambert for a wheel of peculiar construction, in which the paddles or floats always preserve a vertical position, in order to avoid the loss supposed to be sustained by the reaction of the water on the rising side of the wheel, or, as it is termed, the back water. A variety of attempts of this kind have been made, since the invention of steam-boats, for their paddles, but generally they have failed from the number of moving parts, which necessarily create a great additional expense, and a want of that firmness and strength so essential in all water wheels, and more particularly in those attached to steam-vessels. Lambert's water wheel is described in Nicholson's *Practical Mechanic*.

Several other improvements connected with water-mills and water wheels have been proposed and acted upon; but generally they have not so much a reference to their figure and construction as to the means employed to regulate the supply of water and other particulars, which, according to the arrangement adopted in this Treatise, will fall under a subsequent Article. One Machine, however, which although not a water wheel, resembles it in some particulars, and is therefore generally classed amongst them, must be described in this place; this is the inverted chain pump, or

Chain of
buckets.
Pl. viii.
Fig. 8.

(118.) *Chain of buckets.*—This Machine and its action are very easily understood. It is represented in PP, fig. 8, where C, D, G, H, &c. are a number of buckets, united by an endless chain, which passes over two wheels A and B, the upper one being on the axle which is to communicate motion to the mill-work. E being the spout to supply the water to the buckets, and by the preponderance of which on one side motion is produced. The principal advantage of this form of water-mill, if we may be allowed so to denominate it, is that no water is lost by running out of the buckets before they arrive at the lowest part, as is the case with the usual overshot wheel; another is, that the buckets being suspended over a wheel of small diameter, it may be made to revolve more quickly than a wheel of larger diameter, and without increasing the velocity of the descending buckets beyond what is proper for them. This saves wheel work when the Machine is to be employed in work requiring a rapid motion; but, on the other hand, the friction of the chain over the wheel at the top will be very considerable, as it must be made to embrace cogs on its circumference. This is, of course, a disadvantage, yet there are many cases in which such an arrangement would be attended with advantage and convenience.

Pen-
troughs,
penstocks,
&c.

(119.) *Of the different methods of supplying water wheels with water.*—In plate vii. exhibiting the figure and action of water wheels, we have also represented the pentroughs, shuttles, and sluices, sufficiently in detail to give the reader a general idea of the means employed for feeding the mill with water, and regulating the supply. This is, however, a matter of some importance, and requires a little further explanation by means of figures more at large.

Fig. 6.

A method of supplying an overshot wheel, and which is very commonly employed in some Counties, is represented in pl. viii. fig. 6. The water here is let on a little

below the upper part, but may be varied to different heights according to circumstances. In most other methods, if the water is subject to variations in height, which is very commonly the case, the wheel must be adjusted to the lowest head, which is unquestionably a disadvantage, whereas in this the water may vary very considerably, and the whole effect of the water be obtained throughout.

Machinery.

Here A A is the pentrough made of cast iron, the end of which is formed by a grating of broad iron bars; these are inclined in a proper position to direct the water through them into the buckets of the wheel. The spaces between the bars are shut up by a large sheet of leather, which is made fast to the bottom of the iron trough as *a*, and is applied against the bars, the pressure of the water keeping it close in contact with them, so as to prevent leakage. This leather is the shuttle, and by opening it the water is let on. The upper edge of the leather is wrapped round a small roller *b*; the pivots at the ends of this roller are received in the lower ends of two racks, which are made to slide up and down, by the action of two pinions fixed upon the same common axle, which extends across the trough, this axle being turned, raises up and lowers down the roller; and the leather shuttle winds upon it as it descends, or unwinds from it as it ascends, so as to open more of the spaces between the bars, or close them, as may be required. In order to make the roller take up the leather, and always draw it tight, a strap of leather is wound round the extreme ends of the roller, beyond the part where the lower shuttle rolls upon it; these straps are carried above water, and applied on wheels which wind them up with a very considerable tension by the action of a band and weight as shown in the figure.

The water runs over the upper side of the roller through spaces between the bars of the grating into the buckets of the wheel, the descent of the water passing through the bars, and afterwards in falling before it strikes the bottom of the bucket, is found fully sufficient to produce the necessary velocity of the water.

For other pentroughs, penstocks, &c. the reader may consult Gregory's *Treatise of Mechanics*, the *Transactions of the Society of Arts*, vol. xi., and several volumes of the *Repertory of Arts*.

(120.) *Tide-mill* is a particular description of water-mill, worked by the ebbing and flowing of the tide, and which, in consequence of the variable head of water, requires some arrangements in its sluices, &c. different from those above described. Before the invention of the steam engine great ingenuity had been displayed in providing mills for grinding corn by the force of water; and as water-mills on rivers are always considered injurious to the agricultural interests, and form a total impediment to inland navigation, recourse has been had to tide-mills on the side of tide rivers and the mouths of harbours.

It is said that the Romans, so early as the Vth or VIth Century, had constructed tide-mills on the Tiber and other rivers; but if so, all traces of them seem to have been lost, and generally the French are considered to have been the inventors of the modern tide-mill, of which there are various kinds. 1st, those in which the water wheel turns one way when the tide is rising, and the other when it is falling; 2dly, those in which the wheel turns in the same direction in both cases; 3dly, those in which the wheel falls or rises as the tide ebbs or flows; and 4thly, those in which the axle of the water wheel is so fixed, that it shall neither rise nor fall,

the rotary motion being still given to the wheel whether it be partially or wholly immersed in the fluid. One of the finest tide-mills in this Country is that erected on the side of the Thames at East Greenwich, the construction of which is such, that the water wheel rises and falls with the tide. We are indebted to Dr. Gregory's *Mechanics* for the description of this ingenious specimen of mill-work.

This mill is intended for grinding corn, and is competent to drive eight pair of stones. The side of the mill house parallel to the course of the river measures 40 feet within; and as the whole of this may be opened to the river by sluice gates, which are carried down to the low-water mark, there is a 40 feet water way to the mill; through this water way the water passes during the rising tide into a large reservoir, which occupies about four acres of land; and beyond this reservoir is a smaller one, in which water is kept, for the purpose of being let out occasionally at low water to cleanse the whole works from mud and sediment, which would otherwise in time clog the Machinery. The water wheel has its axle in a position parallel to the side of the river, that is, parallel to the sluice gates which admit water from the river: the length of this wheel is twenty-six feet, its diameter eleven feet, and its number of float boards thirty-two. These boards do not each run on one plane from one end of the wheel to the other, but the whole length of the wheel is divided into four equal portions, and the parts of the float boards belonging to each of these portions fall gradually one lower than another, each by one-fourth of the distance from one board to another, measuring on the circumference of the wheel. This contrivance is intended to equalize the action of the water upon the wheel, and prevent its moving by jerks. The wheel with its incumbent apparatus weighs about twenty tons, the whole of which is raised by the impulse of the flowing tide when admitted through the sluice gates. It is placed in the middle of the water way, leaving a passage on each side of about six feet for the water to flow into the reservoir, besides that which in its motion turns the wheel round. Soon after the tide has risen to the highest, (which at this mill is often 20 feet above the low-water mark,) the water is permitted to run back again from the reservoir into the river; and by this means it gives a rotary motion to the water wheel, in a contrary direction to that with which it moved when impelled by the rising tide. The contrivance by which the wheel is raised and depressed, and that by which the whole interior motions of the mill are preserved in the same direction, although that in which the water wheel moves is changed, are very ingenious, and require a distinct description. Let *AB* (pl. viii. fig. 2) be a section of the water wheel, *a'*, *b'*, *c'*, *d'*, *e'*, &c. its floats, *CD* the first cog wheel upon the same axis as the water wheel; the vertical shaft *PE* carries the two equal wallower wheels *E* and *F*, which are so situated on the shaft that one or other of them may, as occasion requires, be driven by the first wheel *CD*; and thus (by what has been said under the article *Reversion of motion*) the first wheel acting upon *F* and *E* at points diametrically opposite, will, although its own motion is reversed, communicate the rotary motion to the vertical shaft always in the same direction. In the figure the wheel *E* is shown in gear, while *F* is clear of the cog wheel *CD*; and at the turn of the tide the wheel *F* is let into gear, and *E* is thrown out; this is effected by the lever *G*, whose fulcrum is at *H*, the other

end being suspended by the rack *K*, which has hold of the pinion *L* on the same axle as the wheel *M*; into this wheel plays the pinion *N*; and the winch *O* on the other end of the axle furnishes sufficient advantage to enable a man to elevate or depress the wallower wheels as required. The action of the lever may be shown more clearly by (fig. 3,) where *ab* is a section of the lever, which is formed of two strong bars of iron, as *ab*; there are two steel studs or pins which work in the grooves of the grooved wheel *I*, and this wheel being fixed on the four rods surrounding the shafts, of which three only can be shown in the figures, as *cde*; the ends of these are screwed fast by bolts to the sockets of the wallower wheels, and they are nicely fitted on the vertical shaft, so as to slide with little friction; thus the wallowers may be raised or lowered upon the upright shaft, while the gudgeon on which it turns retains the same position. When the top wallower is in gear, it rests on a shoulder that prevents it from going too far down; and when the bottom one is in gear, there is a bolt that goes through the top wheel socket and shaft, which takes the weight from the level *c*, at the same time that it prevents much friction on the stud or pins of the lever which works in the grooved wheel *I*.

When the tide is flowing, after the mill has stopped a sufficient time to gain a moderate head of water, the fluid is suffered to enter and fall upon the wheel at the sluice *Q*, (fig. 2,) and the tail water to run out at *R*. The hydrostatic pressure of the head of water acting against the bottom of the wheel frame *S*, and at the same time acting between the folding gates *TW*, which are thus converted into very large hydrostatic bellows, buoys up the wheel and frame, (though weighing, as before observed, nearly twenty tons,) and makes them gradually to rise higher and higher, so that the wheel is never, as the workmen express it, *drowned* in the flowing water; nor can the water escape under the wheel frame, being prevented by the folding gates, which pass from one end to the other of the wheel. In this way the wheel and frame are buoyed up by a head of four feet, and the mill works with a head of five or five feet and a half.

When the tide is ebbing, and the water from the reservoir running back again into the river, it might, perhaps, be expected that, in consequence of the gradual subsiding of the water, the water wheel would as gradually lower; but lest any of the water confined between the wheel frame at *S* and the folding gates *TW* should prevent this, there are strong rack-works of cast-iron by which the wheel frame can be either suspended at any altitude, or gradually let down, so as to give the water returning from the reservoir an advantageous head upon the wheel; then the sluice *R* is shut, and *V* opened as well as *X*, the water entering at *X* to act upon the wheel, and flowing out at *R*. The upper surface of the wheel frame is quadrangular, and at each angle is a strong cast-iron bar, which slides up and down in a proper groove, which admits of this vertical motion, but prevents all such lateral deviation as might be occasioned by the impulsion of the stream.

At each end of the water wheel there is a vertical shaft with wallowers, and a first cog wheel, as *F*, *E*, and *CD*; and each of these vertical shafts turns a large horizontal wheel at a suitable distance above the wallowers, while each horizontal wheel drives four equal pinions, placed at equal or quadrantal distances on its periphery, each pinion having a vertical spindle, on the

Manu-
factures.

upper part of which the upper millstone of its respective pair is fixed; other wheels driven by one or other of these pinions giving motion to the bolting and dressing Machines, and different subordinate parts of the mill, which, however, as we are not describing the interior works, do not belong to this article.

The vertical shaft at each end of the water wheel rises and falls, as we have already stated, with that wheel, but the large horizontal wheel turning with the shaft, and which drives the Machinery, does not rise and fall, but remains always in the same horizontal plane, and in contact with the four pinions it drives. The contrivance for this purpose is very simple, but very efficacious; each great horizontal wheel has a nave, which runs upon friction rollers, and has a square aperture passing through it vertically, just large enough to allow the shaft to slide freely up and down in it, but not to turn round without communicating its rotary motion to the wheel; thus the weight of the wheel causes it to press upon the friction rollers, and retain the same horizontal plane, and the action of the angles of the vertical shaft upon the corresponding parts of the square orifice in the nave, causes it to partake of the rotary motion, such motion being always in one direction in consequence of the contrivance by which one or other of the wallowers E F is brought into contact with the opposite points of the first cog wheel, C D.

In the above case the wheel rises with the tide, but it has been stated, that some tide wheels remain fixed in their place, and revolve even when nearly immersed in the water. Belidor describes a mill of this kind, which works when completely immersed; but a more recent and simple construction is that invented by Mr. Dryden, although it will not bear so much immersion as the former. This is represented in fig. 4. which is an elevation of it, its upper part being supposed to stand a foot or too higher than the tide ever rises; the axis of this wheel remains always in one place, and the wheel work at high water when the head is at B and the tail water at the dotted line A; it will also perform nearly the same work when the head is at C, and the tail water level with the bottom of the wheel. The floats are all set at one and the same angle with the respective radii of the wheel, as may be seen in the figure, and are made so as to have an opening of at least an inch between each float, and the drum boarding or soling of the wheel. This opening is intended to prevent the wheel from being impeded by the tail water, for by this means, as the bucket rises out of the water, there can be no vacuum formed in it, there being a full supply of air, in consequence of which the water leaves the wheel freely. The case is different with regard to wheels made in the common way; for if such are open wheels, the floats are made in such a manner as to go through the tail water if they are immersed any depth in it; or, if they are close, the wheel wants proper vent for the air to prevent the formation of a vacuum in the rising buckets, or, what is called by the miller "sucking up the tail water." At D is planking made circular to fit the wheel pretty close for rather more than the space of two floats, so as to confine the water nearly close to the wheel. E, F, G, H are sluices which are all connected together by the iron bar I, and are lifted with the assistance of a wheel, two pinions, and a winch, the first pinion working into the rack K; these sluices are merely for stopping the wheel when occasion requires, although one might be sufficient to

Fig. 4.

supply the wheel. The rings of this wheel may be made either of cast-iron or of wood; the floats may be iron plates riveted together. The flanches on the arms of the wheel, exhibited in the figure, are intended to facilitate the fixings of the first cog wheel; the ring of the wheel may be fixed to the flanches at the extremity of the arms, and the large flanch made fast to the axle will receive the middle part of the wheel. See Gregory's *Mechanics*.

It still remains for us to describe another engine, worked by water, and employed in some few cases to drive Machinery, but more commonly for grinding, and which is generally dignified by the term mill; that is the

(121.) *Recoil mill* or *Barker's mill*, the former name being derived from its mode of action, and the other from the name of its projector. This Machine is represented as being employed in grinding corn in fig. 5, where A is a pipe or channel which brings water from the reservoir to the upright tube. The water runs down the tube, and thence into the horizontal trunk C, which has equal arms; and, lastly, runs out through holes at d and e, opening on contrary sides near the ends of those arms. These orifices, d, e, have sliders fitted to them, so that their magnitude may be increased or diminished at pleasure.

The upright spindle D is fixed in the bottom of the trunk, and screwed to it below the nut g, and is fixed into the trunk by two cross bars at f; so that, if the tube B and trunk C be turned round, the spindle D will be turned also. The top of the spindle, when the mill is employed for grinding, goes square into the rynd of the upper mill-stone, as in common mills; and, as the trunk, tube, and spindle turn round, the mill-stone is turned round likewise. The lower or quiescent millstone is immediately above the floor K, on which it rests, and in which is the hole to let the meal run through, and fall down into a trough which may be about M. The hoop or case that goes round the millstone rests on the floor K, and supports the hopper in the common way. The lower end of the spindle turns in a hole in the bridge tree G F, which supports the millstone, tube, spindle, and trunk. This tree is movable on a pin at h, and its other end is supported by an iron rod N fixed to it, the top of the rod going through the first bracket O, and having a screw-nut upon it, above the bracket. By turning this nut forward or backward, the millstone is raised or lowered at pleasure. We here suppose the mill employed in grinding, in other cases a wheel may supply the place of the revolving stone. While the tube B is kept full of water from the pipe A, and the water continues to run out from the ends of the trunk, the upper millstone H, together with the trunk, tube, and spindle, turn round; but if the holes in the trunk were stopped, no motion would ensue, even though the tube and trunk were full of water; for, if there were no holes in the trunk, the pressure of the water would be equal against all parts of its sides within.

But when the water has free egress through the holes, its pressure there is entirely removed, and the pressure against the parts of the sides which are opposite to the holes turns the Machine. M. Mathon de la Cour, in 1775, made an improvement in this Machine, by conveying the water from the reservoir, not by a pipe as A D B, in great part of which the spindle turns, but by one which descends from A without the frame L N, till it

Machinery.

Barker's
mill.
Fig. 5.

reaches as low, or lower than G; whence it is conveyed by a curvilinear neck and collar to g, where it enters the arms, as is shown by the dotted lines at the lower part of the figure; a like improvement was made by M. Segner, a German, and afterwards by Ramsay, an American.

The theory of this engine is but little understood, its action and efficiency being very differently stated by different authors. The following appears to us to be decidedly more intelligible, more simple, and more correct than any hitherto given. It is due to Davies Gilbert, Esq., late President of the Royal Society, whose scientific and mechanical knowledge is well known and duly appreciated by the public as well as by the writer of this article. Mr. Gilbert, of course, decides against the mechanical advantage of the Machine, which is, indeed, tacitly admitted by the little use made of it; at the same time it will not be uninteresting to state the grounds of its inefficiency, as, even within a very few years, its merits were supported by some members of a highly useful and respectable society in the Metropolis.

Let every thing be taken in the abstract, and after a manner most advantageous to the Machine. Suppose friction to vanish, and that the perpendicular tube and the arms are so capacious as to allow of the fluid issuing with a velocity equal to what a body would acquire by falling in free space, through an elevation equal to that of the perpendicular tube, or through, what is usually termed, the head. See *Principia*, book ii. sec. 7.

Let l = the space in English feet through which a body freely descends in one second of time.

Then $2l$ = the velocity acquired.

h = the length of the perpendicular tube, or the actual height of the head.

Then $2\sqrt{hl}$ = the velocity due to the head.

Let R = the length of either arm from the centre to the orifice.

= the velocity with which that point moves in revolving, expressed by feet in a second.

Then $\frac{x^2}{2lR}$ = the centrifuga. force at the orifice.

And since the force exerted by each particle of the fluid varies as its distance from the centre,

$\frac{x^2}{2lR} \times \frac{R}{2} = \frac{x^2}{4l}$ = the whole pressure from centrifugal force. An expression independent of the length of the arm; and the slightest reflection will make it appear that no alteration can arise from deflecting the form of the arm out of a straight line. Then, since the pressure exerted by the actual head is expressed by its height h , and the pressure from the centrifugal force by $\frac{x^2}{4l}$

$h + \frac{x^2}{4l}$ = the pressure sustained, or the virtual head,

and $\left(h + \frac{x^2}{4l}\right) \times x$ = the efficiency applied to the Machine, in relation, however, not to the expenditure of fluid corresponding to the height h , but to an expenditure

greater in the proportion of $\sqrt{1 + \frac{x^2}{4hl}}$ to 1. But

a portion of this efficiency must, of necessity, be expended in giving the rotary velocity (x) to the quantity

VOL. VII.

of fluid issuing = $\sqrt{1 + \frac{x^2}{4hl}}$. Now the height due Machinery.

to x is $\frac{x^2}{4l}$, consequently $\sqrt{1 + \frac{x^2}{4hl}} \times \frac{x^2}{4l} \times x$ = the expenditure of efficiency in producing the rotary motion;

and $\left(h + \frac{x^2}{4l} - \sqrt{1 + \frac{x^2}{4hl}} \times \frac{x^2}{4l}\right) \times x$ = the efficiency applied to the Machine capable of producing duty.

Now substitute for x the velocity due to h , ($2\sqrt{hl}$)

multiplied by an arbitrary quantity y ; then $\sqrt{1 + \frac{x^2}{4hl}}$

(or the quantity of fluid issuing) = $\sqrt{1 + y^2}$, and

$2h^{\frac{3}{2}}l^{\frac{1}{2}}\{(1 + y^2)y - y^3\sqrt{1 + y^2}\}$ = efficiency, and dividing by $\sqrt{1 + y^2}$

$2h^{\frac{3}{2}}l^{\frac{1}{2}}\{y\sqrt{1 + y^2} - y^3\}$ =

the efficiency that would be applied if no more fluid issued than what is due to the actual head (h .)

The following Table exhibits the value of both these functions, taking (y) from 0, (where the duty must obviously be nothing,) by steps of $\frac{1}{10}$ ths, to 1.25; after which the duty becomes negative.

y	The Duty for a given Expenditure of Fluid on the Function $y\sqrt{1+y^2}-y^3$.	y	The Duty performed actually by the Expenditure of Fluid on the Function $y+y^2-y^3\sqrt{1+y^2}$.
.05	.04994	.05	.05000
.10	.09950	.10	.10000

1.15	.23170	1.15	.35311
1.20	.14646	1.20	.22878
1.25	.04785	1.25	.07660
1.28	.01803	1.28	.02929
	Negative.		Negative.

The first of these functions reaches the maximum, when y exceeds .75 or $\frac{3}{4}$ by two or three thousandths, and the second when y is about .83.

From an inspection of the Table, it appears, that when the Machine is moving with the velocity productive of its greatest relative effect, namely, at three quarter parts of the velocity with which the fluid would issue under a pressure equal to that of the actual head, that the duty exceeds by a mere trifle one half of the efficiency expended; and from thence it obviously follows, that the recoil engine cannot in any case be employed with

Manufac-
tures.

advantage. The water wheel, whenever the fall does not exceed forty or fifty feet, and the pressure engine, provided with an air vessel, in all cases where the fall is greater, receive an efficiency almost equal to the whole expended, instead of one half; and in practice, the duty will reach three quarters. The wheel, moreover, possesses a self-regulating power, sufficiently accurate for the present illustration, and somewhat analogous to the isochronism of the pendulum; that is, the actual weight of water on the wheel, and its velocity of rotation, must always be reciprocal to each other; thus maintaining a given efficiency, independent of velocity. The received efficiency of a water wheel being represented by the power of water passing over it, multiplied by the fall in feet, minus the height due to the velocity with which the periphery moves in its rotation. But in the recoil engine, the moving power is expending at the rate due to the height even when the Machine is actually standing still; and when it moves with a velocity exceeding that due to the length of the head, in the proportion of about 128:1, (where the duty is again nothing,) the moving power will be expended at the increased rate $\sqrt{1 + (1.28)^2} : 1$.

Hence too may be easily shown the utter impossibility of executing a plan, which would not, indeed, deserve any notice, were it not that two ingenious practical engineers have within these few years, although at different times, and independently of each other, incurred large expense, and employed much pains in attempting to apply steam on the principle of recoil. *Phil. Trans.* 1827.

Authors on
mills and
mill work.

(122.) The following list of authors who have written on the subject of mills may be both useful and instructive to the general reader. We are indebted for it to Dr. Gregory's *Mechanics*.

Künstliche Abriss, allerhand Wasser-Wind-Ross- und Hand-Mühlen, &c. Von Jacob. de Strada, à Rosberg, 1617.

Georg. Christoph. Luerner, *Machina torrentica nova; oder, Beschreibung der neu erfundenen Drehmühlen*, 1661.

Theatrum Machinarum Novum; das ist, neu vermehrter Schauplatz der mechanischen Künste handelt von allerhand Wasser-Wind-Rossgewicht- und Hand-Mühlen. Von Geo. And. Bocklern, 1661.

Contenta discursus Mechanica, concernentis Descriptionem optimæ formæ Velorum Horizontalium pro usu Molarum, necnon fundamentum inclinorum Velorum in Navibus; habita coram Societate Regia à R. H. translata ex collectionibus philosophicis M. Decum, 3. p. 61. 1681.

Dissertatio Historica de Molis quam præside Joh. Phil. Treuer, defend. Joh. Tob. Mühlberger, Ratisbonens, Jenæ, 1695.

Martin Marten, *Wiskundige beschonwinge der Wind of Wadermoolens, vergeleken met die van den heer Johann. Lulofs*, Amsterdam, 1700.

Vollständige Mühlen-baukunst, von Leonhard Christoph. Sturm, 1718.

A Sketch of the Properties and Advantages of Sutton's Patent Gravitated Sails for Windmills, by W. Smith, Hesleden, 1807.

Four Essays on Practical Mechanics; the first on Water-wheels, the second on the Steam Engine, the third on Mills, and the fourth on the Simplification of Machinery, by Thomas Fenwick, 1801.

The Transactions of the Society of Arts, &c. several volumes of which contain many ingenious improvements in mill work. See also the *Repertory of Arts*, in several volumes of which are described various patented inventions on the same subjects.

OF THE STEAM ENGINE, AND ITS APPLICATION TO MINING, NAVIGATION, &c.

(123.) Before attempting any illustration of the mechanical operations of this important engine, it will be necessary to establish the laws of the great agent of all its action, STEAM. It is only after having fully understood the nature of this elastic fluid or vapour, the laws which appertain to its generation and condensation, its increase or decrease of elasticity, resulting from and depending upon an increase or decrease of temperature, that we can appreciate the value of the many ingenious and important changes, not only in form but in principle, which it has undergone since its first rude introduction as an agent of mechanical force. In its primitive state its power was of very limited extent, and its application restricted to one single operation, *pumping*. We have to trace it from this state through various changes, till we find it employed in almost every description of Manufacture, performing the labour in this Country of more than three millions of men, impelling vessels of immense tonnage from port to port, not only along rivers and sea-coasts, but across seas and oceans, with a degree of certainty and security which could never have been contemplated even by the most sanguine of the original projectors of this modern application of its power. On land we find it superseding the use of horses, and doubling the speed of the swiftest of these animals, and thus reducing the time of transit between places which, only a few years back, was the business of a day, to a pleasant and easy ride scarcely exceeding an hour. It will be our business in the following pages to trace and illustrate these extraordinary inventions and improvements; and, in order to preserve their chain of connection as entire as possible, we propose, in the first place, to treat of the power, the generation, and condensation of steam, and the several laws by which its power is regulated; thus separating the chemical and philosophical from the mechanical character of the engine.

Of Steam.

(124.) *Steam* may be defined to be the invisible vapour of water which is given off by it at all known temperatures under certain degrees of pressure.

Manufac-
tures.

This does not agree with the popular idea of steam, according to which it is the visible moist vapour arising from all bodies which contain juices easily expelled from them by heat, not sufficient for their combustion, being distinguishable from smoke by not containing any soot, and by being condensible by cold. This visibility of steam, however, is so far from being an essential characteristic of, that it is altogether foreign to it, and can only have place when it is mixed with or disseminated in air, or in some elastic fluid colder than itself.

Vapour is nearly synonymous with steam; the latter term, however, is commonly limited to express the vapour from water; the former is more general, being applied to any condensible gas.

Heat is a quality diffused through all bodies in nature, and has a constant tendency to an equilibrium; that is, when accumulated in any body, or parts of a body, in greater abundance than in others, the hotter body gives off quickly a portion of its own heat to the surrounding bodies till an equilibrium is established.

Caloric is a term used to express the cause or matter of heat in bodies; its nature is not at all understood, but it is generally, and more simply, treated of as a very subtle, elastic, and imponderable fluid.

Specific heat.—When there is an equilibrium of heat amongst adjoining bodies, and a fresh supply of it is introduced, different bodies will be found to have absorbed different quantities of this supply; when the whole are again in equilibrio, and the peculiar quantity of this additional heat absorbed by each body is denominated the specific heat of that body. Tables of the specific heat of bodies have been formed by different experiments; that of water at 60° of Fahrenheit being commonly assumed as unity.

Capacity of heat is sometimes confounded with the specific heat of bodies; for as one body absorbs more heat than another to raise its temperature a certain number of degrees, it may be said to have a greater capacity for heat: others, however, distinguish between the two terms, by limiting the term *capacity for heat* to the relation between the whole quantity of heat in bodies of the same temperature; and *specific heat* to express, as we have already defined it, the quantity necessary to produce a certain change of temperature. A change of state of bodies is frequently the result of an increase or abstraction of heat. Thus ice by an increase of heat becomes water, and water by an increase of heat becomes vapour or steam; so, conversely, by abstracting heat, steam becomes water, and water ice, and in these different states the same matter has a different capacity for heat. Steam has a greater capacity for heat than water, and water than ice. This difference in the conversion of water into steam is very great. When a given quantity of water heated to 212° is converted into steam of the same temperature, the heat necessary to produce the change would raise the temperature of about five and a half times as much water from the freezing point 32° to the boiling point 212°.

Of the Latent Heat of Steam.

(125.) It appears from the last paragraph that a large quantity of heat is absorbed by the water in a state of steam, which is not evident to our sensations nor to the thermometer: this heat thus absorbed is denominated *latent heat*; it is given out again when the steam is condensed into water.

Experi-
ments on
the latent
heat of
steam.

The heat combined or disengaged by a change of the state of a body, or its latent heat, is measured in the same manner as specific heat, that is, by the quantity of heat necessary to raise the temperature of a certain quantity of water at 60° one degree.

This great absorption of heat in water passing from its liquid into a gaseous form is of course a very important consideration in the economy of the Steam Engine, and was a part to which the talents and ingenuity of Watt were directed very early in his progress of improvement in this important engine. It was no doubt the distinguished Philosopher Dr. Black, who first discovered, or rather, perhaps, he was the first who illustrated that a change in the state of bodies required a certain addition or abstraction of heat; that the quantity is different for different bodies, and also different according to the nature of the change. The importance of this discovery, and the theory of latent heat by which it is explained, are highly important to general science, and have undoubtedly an immediate application to the economy of this engine; but their importance has been perhaps rather overrated, being sometimes represented as forming the groundwork of all its modern improvements. It will be seen, however, by the following quotation from a letter of Mr. Watt to Sir David Brewster, as well as from the nature of the discovery, that this theory, beautiful as it is in itself, was not essential to the applications which Watt made of the power of steam as a propeller of his engine. Dr. Robison seems to have first fallen into this error, in his article Steam Engine in the *Encyclopedia Britannica*, an error which has spread from that source through many other historical sketches of the steam engine, not only in this Country but in France. These at length called forth some remarks from Mr. Watt, not long before his death, addressed to Sir David Brewster, when engaged in a republication of Dr. Robison's Works. See the Introduction to vol. ii. These it will be but justice towards this ingenious mechanician to quote. The subject is undoubtedly intimately connected with the due performance of the steam engine, whose operation depends upon a constant rarefaction of water into steam, and of the condensation of steam into water; still, however, a knowledge of the fact, without any knowledge of the actual theory of its action, was all that was essentially necessary to Mr. Watt; and, therefore, to attribute all his brilliant discoveries to the theory of Dr. Black, is to do him an injustice, and which he thought necessary, at the recommendation of his friends, to remark upon in the Work to which we have referred. These remarks, as above stated, are given in the form of a letter to Sir David Brewster, of which we think it right to give the following extract. After stating the nature of some notes and alterations he had found it necessary to make in Dr. Robison's account relative to the mechanical arrangements of his engine, he says, "Here it was my intention to have closed this Letter; but the representations of friends, whose opinions I highly value, induce me to avail myself of this opportunity of noticing an error into which not only Dr. Robison, but apparently also Dr. Black, has fallen, in relation to the origin of my improvements upon the steam engine, and which, not having been publicly controverted by me, has, I am informed, been adopted by almost every subsequent writer upon the subject of Latent Heat."

"Dr. Robison, in the article Steam Engine, after passing an encomium upon me, dictated by the partiality of friendship, describes me as the 'pupil and intimate friend of

Watt's re-
marks on
the subject
of latent
heat.

Manufactures.

Dr. Black; a description which, not being there accompanied with any inference, did not particularly strike me at the time of its first perusal. He afterwards, in the dedication to me of his edition of Dr. Black's *Lectures upon Chemistry*, goes the length of supposing me to have professed to owe my improvements upon the steam engine, to the instructions and information I had received from that gentleman, which certainly was a misapprehension; as, though I have always felt and acknowledged my obligations to him for the information I had received from his conversation, and particularly for the knowledge of the doctrine of Latent Heat, I never did, nor *could*, consider my improvements as originating in those communications. He is also mistaken in his assertion, page 8 of the preface of the above Work, that 'I had attended two courses of the Doctor's Lectures;' for, unfortunately for me, the necessary avocations of my business prevented me from attending his or any other Lectures at College; and as Dr. Robison was himself absent from Scotland for four years at the period referred to, he must have been misled by erroneous information. In page 184 of the Lectures, Dr. Black says, 'I have the pleasure of thinking that the knowledge we have acquired, concerning the nature of elastic vapours, in consequence of my fortunate observation of what happens in its formation and condensation, has contributed, in no inconsiderable degree, to the public good, by suggesting to my friend Mr. Watt of Birmingham, then of Glasgow, his improvement in this useful engine.' (Meaning the steam engine, of which he is then speaking.) There can be no doubt, from what follows in his description of the engine, and from the very honourable mention which he has made of me in various parts of his Lectures, that he did not mean this to lessen any merit that might attach to me as an inventor, but on the contrary, he was always disposed to give me fully as much praise as I deserved. And were that otherways doubtful, it would, I think, be evident from the following quotation from a Letter of his to me, dated 13th February, 1783, where speaking of an intended publication by a friend of mine, on subjects connected with the history of steam, he says, 'I think it is very proper for you to give him a short account of your discoveries and speculations, and particularly to assert clearly and fully your sole right to the honour of the improvements of the steam engine;' and in a written testimonial which he very kindly gave on the occasion of a trial at law against a piracy of my invention, in 1796—7, after giving a short account of the invention, he adds, 'Mr. Watt was the sole inventor of the capital improvement and contrivance above mentioned.'

"Under this conviction of his candour and friendship, it is very painful to me to controvert any assertion or opinion of my revered friend; yet, in the present case, I find it necessary to say that he appears to me to have fallen into an error; and I hope, in addition to my assertion, to make that appear by the short history I have given of my invention in my notes upon Dr. Robison's Essay, as well as by the following account of the state of my knowledge previous to my receiving any explanation of the doctrine of latent heat, and also from that of the facts which principally guided me in the invention.

"It was known very long before my time, that steam was condensed by coming into contact with cold bodies, and that it communicated heat to them; witness the common still, &c. &c.

"It was known by some experiments of Dr. Cullen

and others that water and other liquids boiled in vacuo at very low heats; water below 100°.

Machinery.

"It was known to some philosophers, that the capacity or equilibrium of heat, as we then called it, was much smaller in mercury and tin than in water.

"It was also known that evaporation caused the cooling of the evaporating liquid, and bodies in contact with it; I had myself made experiments to determine the following facts:—

"1. The capacities for heat of iron, copper, and some sorts of wood, comparatively with water. Similar experiments had also subsequently been made by Dr. Irvine, on these and other metals.

"2. The bulk of steam as compared with that of water.

"3. The quantity of water which could be evaporated in a certain boiler by a pound of coals.

"4. The elasticities of steam of various temperatures greater than that of boiling water, and an approximation to the law which it followed at other temperatures.

"5. How much water in the form of steam was required every stroke by a small Newcomen's engine, with a wooden cylinder six inches in diameter, and twelve inches long in the stroke.

"6. I had measured the quantity of cold water required in every stroke to condense the steam in that cylinder, so as to give it a working power of about seven pounds on the inch.

"Here I was at a loss to understand how so much cold water could be heated so much by so small a quantity in the form of steam, and applied to Dr. Black, as is related in the short history, p. 116. note, and then first understood what was called latent heat.

"But this theory, though useful in determining the quantity of injection necessary where the quantity of water evaporated by the boiler and used by the cylinder was known, and in determining by the quantity and heat of the hot water emitted by Newcomen's engines, the quantity of steam required to work them, did not lead to the improvements I afterwards made in the engine. These improvements proceeded upon the old established fact, that steam was condensed by the contact of cold bodies, and the latter known one, that water boiled in vacuo at heats below 100°, and, consequently, that a vacuum could not be obtained unless the cylinder and its contents were cooled every stroke to below that heat. These, and the degree of knowledge I possessed of the elasticities of steam at various heats, were the principal things it was necessary for me to consider in contriving the new engine. They pointed out that, to avoid useless condensation, the vessel in which the steam acted upon the piston ought always to be as hot as the steam itself; that to obtain a proper degree of exhaustion, the steam must be condensed in a separate vessel, which might be cooled to as low a degree as was necessary without affecting the cylinder; and that as the air and condensed water could not be blown out by the steam, as in Newcomen's, they must be extracted by a pump, or some other contrivance; that, in order to prevent the necessity of using water to keep the piston air tight, and also to prevent the air from cooling the cylinder during the descent of the piston, it was necessary to employ steam to act upon the piston in place of the atmosphere. Lastly, to prevent the cylinders from being cooled by the external air, it was proper to inclose it in a case containing steam; and again to enclose that in a case of wood, or of some other substance which transmitted heat slowly.

tures.

Black's ex-
periments
and deduc-
tions.

"Although Dr. Black's theory of latent heat did not suggest my improvements on the steam engine, yet the knowledge upon various subjects which he was pleased to communicate to me, and the correct modes of reasoning, and of making experiments, of which he set me the example, certainly conduced very much to facilitate the progress of my inventions; and I still remember with respect and gratitude the notice he was pleased to take of me when I very little merited it, and which continued throughout his life.

"To Dr. Robison I am also bound to acknowledge my obligations for very much information and occasional assistance in my pursuits; and, above all, for his friendship, which ended only with his life; a friendship which induced him, when I was beset with a host of foes, to come to London in the depth of Winter, and appear as a witness for me in a Court of Justice, while labouring under an excessively painful disorder, which ultimately deprived him of life. To the remembrance of that friendship is principally owing my taking upon myself the office of his commentator at my advanced age."

It has been thought right to give this rather long extract, as it is very desirable, in a discovery or improvement of such immense national advantage as that attending the modern principle of the steam engine, that the full merit of every step in the progress of the same should be attributed to its proper authors. We must now proceed with our illustrations.

(126.) The additional heat in the vapours or steam of any liquid is not very easily determined; but since the discovery to which we have alluded by Dr. Black, experiments have been made by several Philosophers, distinguished for their accuracy and skill in such researches. Dr. Black's method is simple and easily tried, but it is not sufficiently accurate. When a vessel containing water is placed on a fire, the water gradually becomes hotter till the temperature reaches 212° ; but after that its temperature does not increase, the water is flying off in steam, and the heat not raising the temperature higher, as we know it would do if the vessel were closed, we must conclude that the heat, which would be communicated to the water in a close vessel, combines with the steam in an open one, and yet does not increase the temperature of that steam to more than that of boiling water. To ascertain the quantity of heat which is thus combined with the steam, Dr. Black put some water in a tin plate vessel, upon a piece of red-hot iron. The water was at the temperature of 50° , in four minutes it began to boil, and in twenty minutes it was all evaporated. During the first four minutes it had received $212^{\circ} - 50^{\circ} = 162^{\circ}$ of heat, or $40\frac{1}{2}^{\circ}$ per minute. If we suppose it received the same quantity per minute during the whole process, the whole quantity of heat $40\frac{1}{2}^{\circ} \times 20 = 810^{\circ}$; and this had converted the whole of the water into steam; but it is not indicated by the thermometer, the temperature of this being never more than 212° ; this 810° therefore Dr. Black considered as latent heat. But the result is obviously inaccurate, because steam is formed during the heating of the water to the boiling point, and the vessel is losing heat from its surface in unequal quantities, and the effect of the fire is also unequal, being less as the heat of the water increases. This, however, was but a first attempt at forming an estimate, since which much more accurate methods have been adopted, and a tolerable certain result has been at length obtained.

(127.) Mr. Watt, in 1780, made several experiments on

this subject, which are described by him in the article we have already quoted, and from the result of those on which he could place the most reliance, he obtained 950° for the additional heat in the steam of water. These experiments were made by condensing steam into water, and measuring accurately the increase of temperature produced by the absorption of the latent heat of the steam; and in a similar way experiments were made by Count Rumford, Mr. Southern, and, more lately, by Dr. Ure.

In 1803, Mr. Southern and Mr. W. Creighton made several experiments of this kind under different barometric pressures, and at different temperatures, the mean results of which gave 954° .

In other experiments, made under the same pressures and temperatures, the quantities of heat were found 942° and 950° ; mean 949° .

(128.) Another way of arriving at an estimate of this latent heat is by means of Papin's digester, in which water may be heated to 400° without boiling. Now if, when heated to this degree, the mouth of the vessel be suddenly opened, it is found that one-fifth of the water rushes out in steam, and the remaining four-fifths is of course reduced to 212° , consequently 188° have been carried off. Dividing the whole quantity of water into five parts, the one-fifth part, carried off in the form of steam, has absorbed not only its own 188° , but also the same quantity from each of the other four parts, the whole being reduced to 212° ; it has, therefore, absorbed $188^{\circ} \times 5 = 940^{\circ}$. This estimate, however, is rather rough, as it depends so much upon the actual portion of water remaining in the vessel.

(129.) The experiments of Count Rumford give a higher result; and as his skill in such inquiries was well known, great credit has been given to his results. In these experiments the heat was measured by means of the temperature communicated to a copper vessel filled with water, which he called his calorimeter. Within this was placed a thin serpentine pipe of copper, containing the steam to be condensed; hence the fluids did not mix together, and loss by the escape of vapour was prevented.

The water which the calorimeter contained was at a lower temperature than that of the room by 5° or 6° ; and when the thermometer of the calorimeter indicated an augmentation of temperature of 10° or 12° , an end was put to the experiment. The water produced by the condensation of the vapour in the pipe was carefully weighed, and from its quantity, as well as from the heat communicated to the calorimeter, the heat developed by the vapour in its condensation was determined. As a small part of the heat communicated to the calorimeter was produced from the cooling of the water condensed in the pipe after the vapour had been changed into water, an account was kept of this heat. It was supposed that the water at the moment of condensation was at the temperature of 212° , being that of boiling water, and it was determined by calculation, what part of the heat communicated to the calorimeter must have been due to the boiling water.

The following are the details and results of two of his experiments made January 21, 1812. The duration of each was from ten to eleven minutes. The water had been boiled for some time to drive out the air which it contained before the steam was directed into the serpentine pipe of the calorimeter.

				Mean.	1040.8

This result is considerably higher than those above stated, and higher than those more recently obtained by Dr. Ure, although his also are greater than the former.

Ure's experiments.

(130). Dr. Ure's experiments were undertaken in 1817, and were communicated to the Royal Society, and published in the *Philosophical Transactions* for 1818.

His apparatus consisted of a glass retort of very small dimensions, with a short neck inserted into a globular receiver of very thin glass, about three inches in dia-

meter. The glass was fixed steadily in the centre of Machinery 32,340 grains of water, at a known temperature, contained in a glass basin. Of the liquor whose vapour was to be examined, 200 grains were introduced into the retort, and rapidly distilled into the globe by the heat of an Argand lamp. The temperature of the air was 45°, that of the water in the basin from 42° to 43°, and the rise of temperature occasioned by the condensation of the vapour never exceeded that of the air by four degrees. As the communication of heat is very slow in bodies which differ little in temperature, the air could exercise no perceptible influence on the water in the basin during the experiment, which was always completed in five or six minutes. A thermometer of great delicacy was continually moved through the water, and its indications were read off by the aid of a lens to a small fraction of a degree.

The distillation was rapidly performed, and the author states that in the numerous repetitions of the same experiment, the accordance was every thing that could be desired. The following Table gives the mean result for water and some other fluids.

Liquid.	Specific Gravity.	Temperature of the Water in the Basin.			Boiling Point.	Heat of Conversion into Vapour.
		Beginning.	End.	Difference.		
Water	1.000	42.5°	49°	6.5°	212°	942° *
Alcohol	0.825	42	45	3	175	425.50
Sulphuric ether	0.7	42	44	2	112	302.60
Oil of turpentine	0.888	42	43.5	1.5	316	146.0
Petroleum	0.75	42.5	44	1.5	306	150.0
Nitric acid	1.494	42	45.5	3.5	165	517.0
Ammonia	0.978	42	47.5	5.5	140	840.0
Vinegar	1.007	42.5	48.5	6	...	870.0

Dr. Ure has since corrected these numbers for the loss of heat not included in his first deductions, and he makes thus the heat of conversion for water into steam 1000°, which is about a mean between all we have given, and is probably not far from the truth.

The preceding statements contain the best information we at present possess relative to the conversion of water into steam, and the quantity of heat absorbed in the conversion, which is insensible to the thermometer, and which, perhaps, may now be more advantageously stated as a general rule as follows, *i. e.* That it would require 5½ times the quantity of heat to convert a given quantity of water at 212° into steam, that would raise the temperature of the same water from 32° to 212°.

Elasticity of steam.

(131.) *On the elastic force of steam in contact with water.*—It has been seen, and the fact is generally known, that the elastic force of steam at 212° is equal to the pressure of the atmosphere, or to about 14½ pounds on a square inch; it remains for us now to report those experiments which have been undertaken to determine its elasticity at other degrees of temperature above and below 212°. Its elastic power below 212° has little to do with the application of steam as a motive power, but it is involved in the condensation, and therefore, as a part of the general inquiry, we shall give some of those

results which have been obtained at low temperatures as well as others at very high temperatures, although, perhaps, neither extreme will ever find a practical application; but theoretically they are both extremely valuable, in verifying formulæ intended to express the law of relation between different degrees of heat and the corresponding elastic force of steam.

It is not, perhaps, within our province, and is certainly not consistent with our limits, to enter into a minute description of the various methods followed by different experimenters to determine the elastic power of steam at different temperatures; at the same time, the several results thus obtained, which may be tabulated within narrow limits, will be both interesting and useful; it is proposed, therefore, in the following Table to exhibit the results which have been obtained by many very able Philosophers, and to describe one or two methods of conducting the experiments which have been thought most perfect; and lastly, to compare these several results with the different formulæ which have been given with a view of expressing the relation between the temperature and the elastic force of steam.

Tabulated elasticities of steam by different authors.

* The numbers in this column are given as corrected by Mr. Tredgold, they being erroneously given in the article referred to.

Manufac- TABLE showing the Elastic Power of Steam at different Degrees of Temperature, as resulting from the Machinery. Experiments of different Authors, within the Limits of six Atmospheres. The Degrees are those of Fahrenheit's Thermometer.

						300	139.700				
						310	161.300				
						312	167.000				
						312	165.5				

The above are the principal results that have been obtained relative to the elastic power of steam within the limits of six atmospheres. Since these, however, experiments have been carried to the extent of twenty-four atmospheres, which will be given below; but it will be proper first to describe the method adopted by Dr. Robison and Dr. Ure, in obtaining the results stated in the preceding Table; these being not only free from several objections which have been made against other methods, but the latter in particular is also very simple, and applicable to similar inquiries for other liquids.

(132.) Dr. Robison's apparatus consisted of a small digester of copper A B C D, (pl. ix. fig. 1,) the top of which had a thermometer inserted through the centre, and a loaded valve at V, with a third hole for inserting a barometer tube S G F to ascertain the force at lower temperatures than 212°. The force of the higher temperatures was measured by the steelyard on the valve, and a plug was inserted in the place of the tube S G F; but the results with the valve were irregular and not satisfactory. Hence the glass tube M N K (fig. 1, a) having a cistern, L, for mercury, was adapted to the hole in the digester, and instead of measuring the force by the valve, it was measured by the ascent of the mercury in the tube M N. The digester was heated by a lamp.

To determine the pressure at temperatures below 212°

the tube S G F was inserted as in the figure, and a basin of mercury provided at F. The lamp being applied, the water in the digester produced steam till it issued at both the pipe and the valve F, so as to expel the air; the lamp being removed, and both the valve and tube being closed, the latter by immersing it in the mercury, the mercury rose in the tube F G, as the apparatus cooled, and the heights corresponding to different temperatures were noted; like observations were made as it was reheated. To determine the pressure at higher temperatures with the apparatus, the end K of the tube M N K was inserted at E, and as the temperature increased, the pressure of the steam in the cistern L caused the mercury to ascend, and consequently afforded the means of measuring the force of the steam.

The objection to this mode of trial is that the temperature of the mercury must be continually changing during the trial, and steam must either be condensing or generating on its surface during the time of observation. At each observation the temperature of the whole of the apparatus ought to be the same, and then the column exhibiting the pressure ought to be reduced to its equivalent at the mean temperature. The only observation in which these circumstances could have place was that which appears to have been made when the thermometer was at 42°, then the column in the syphon was 27.7 and the barometer stood at 29.84; the difference in the

Manufac-
tures.

Fig. 2, 3, 4.

force of steam at 42° , and is 0.14 inches. By cooling down to 32° the force was not perceptibly different, and we know from later trials that this is nearly correct.

(133.) In plate ix. fig. 2 represents the construction employed by Dr. Ure for temperatures under and a little above the boiling point, fig. 3 and 4 were used for high temperatures; the last is the more convenient of the two. It was suspended from a lofty window ceiling, and placed with the tube L D in a truly vertical position by means of a plumb line. One simple principle pervades the whole train of experiments, which is, that the progressive increase of elastic force is developed by heat from the liquid incumbent on the mercury at *l*, measured by the length of column which must be added over L, in order to restore the quicksilver to its primitive level at *l*. These two stations, or points of departure, are nicely defined by a ring of fine platina wire twisted round the tube.

At the commencement of the experiments, after the liquid, well freed from air, has been let up, the quicksilver is made to coincide with the edge of the ring L, by cautiously pouring mercury in a slender stream into the open leg of the syphon D. The level ring at L is then carefully adjusted.

From the mode of conducting the experiments there remained always a quantity of liquid in contact with the vapour, a circumstance essential to accuracy in this research. Suppose the temperature of the water or the oil in A (fig. 2) to be 32° , as denoted by a delicate thermometer, or by the liquefaction of ice, and let L D be a column equal to the atmospheric pressure; communicate heat to the cylinder A, by means of two Argand flames playing gently against its shoulder at each side.

When the thermometer indicates 42° modify the flames, or remove them so as to maintain an uniform temperature for a few minutes. Then the elasticity will be faithfully represented and measured by the mercurial column which we must add over D, in order to return the quicksilver to the line *l*, its zero or initial level.

A piece of cork, E, is fixed between the parallel legs of the syphon to sustain it, and to serve as a point by which the whole is steadily suspended.

For temperatures above the boiling point, the part of the syphon under E is evidently superfluous, merely containing in its two legs a useless weight of equipoised mercury. Accordingly for high heats, either apparatus (fig. 3 or 4) is employed, and the same method of procedure is adopted. The aperture at O (fig. 3) admits the bulb of the thermometer, which rests against the tube. The recurved part of the tube is filled with mercury, and then a little liquid is passed through it to the sealed end. Heat is applied by an Argand flame to the bottom of C, which is filled with oil or water, and the temperature is kept steadily at 212° for some minutes. Then a few drops of quicksilver may require to be added at D, till L and *l* be in the same horizontal plane. The further conduct of the experiment differs in no respect from what has been described. The liquid in C is progressively heated, and at each stage mercury is progressively added over L to restore the initial level or volume at *l*, by equipoising the progressive elasticity; the column above L being the accession of elastic force: when it is wished to extend this column very high, the vertical tube requires to be placed for support in the groove of a long wooden prism.

We cannot enter into a description of the other methods which have been had recourse to in the pursuit of

this inquiry; but to such of our readers as are desirous of examining the different processes, the following references may be useful. Watt's experiments are detailed in Robison's *Mech. Phil.* by Brewster, vol. ii. p. 33, 34. Dr. Robison's own experiments, as above stated, are given in the same volume, p. 36. Dalton's, in the *Manchester Memoirs*. See also *Phil. Journal*, by Nicholson, vol. vi.; *Annals of Philosophy*, vol. x.; Southern's; Robison's *Mech. Phil.* vol. ii. p. 173; Taylor's *Phil. Mag.* vol. ix.

(134.) In no one of the preceding experiments the pressure exceeded six atmospheres, but the great importance which was attached to obtaining a perfect knowledge of the elastic power of steam at higher temperatures, induced the French Government to request the members of the Institute of France to undertake a new series of experiments on this subject. These were placed under the able direction of MM. Baron de Prony, Arago, Girard, and Du Long, who in 1830 made their Report to the Institute, by whom it was addressed and presented to the Minister of the Interior.

These results are too important to be passed over in silence, although it will be impossible for us to explain the many details which necessarily attend such a course of experiments, in order to ensure that degree of precision which it was so desirable they should possess. The reader, however, without this, will not doubt of their accuracy, from the known character of the distinguished Philosophers by whom the experiments were conducted, and the means which were put into their hands by the French Government. Those who are desirous of examining the whole in detail, are referred to the *Exposé des Recherches faites par Ordre de l'Académie Royale des Sciences pour déterminer les Forces Elastiques de la Vapeur d'Eau à de hautes Températures*, published by Firmin Didot, Frères, Paris, 1830.

The experiments may be divided into two parts: first, those by which the compression of the same volume of air was ascertained for different pressures of mercury, varying from one atmosphere to 27 atmospheres, that is from 30 inches of mercury to nearly 70 feet; and secondly, those which, by employing the compressions thus ascertained, were made to determine the elastic power of steam, till that power amounted to the pressure of 24 atmospheres.

(135.) The apparatus by which the first course of experiments were conducted is shown in plate ix. fig. 5, where *s* represents a metallic vessel with two tubes projecting from its bottom, and containing about 100 pounds of mercury. This vessel was furnished at top with a forcing pump L. To the end of the tube *a* was fixed a barometer tube *aa* containing air, and this again was covered by a larger glass vessel, filled with water from the cistern *e*, which water was discharged at *r*, as fast as it was supplied at *a*, whereby the temperature of the air in the tube *aa* was preserved of the uniform temperature of the water in the cistern *e*. To the other extremity of the tube was fixed a length of barometer tube of two metres, and thirteen such tubes being accurately united by the means described in the *Exposé*, were placed end to end to the height of more than $85\frac{1}{2}$ feet English measure. The diameter of the tubes was 5 millimetres, or about two-tenths of an English inch, and of the same thickness, the tube *aa* having also the same diameter and thickness, and its length 1.7 metres, or 67 English inches. The weights and pulleys shown at P P were employed to relieve the lower tubes from the weight of

Machinery

Elastic power of steam at high temperatures.

Experiments made by order of the French Government by Members of the Institute.

Manufactures.

those above them, and were of course repeated at every stage or point of union of the tubes. The scale *g* was for ascertaining the elevation of the mercury, as the scale shown on the other branch was for measuring the same in the tube *a a*, or the compression of the air; the apparatus shown at *q, r, u* was rendered necessary for adjusting the vernier, in consequence of the interposed water in the outer tube *m m'*, the temperature of which was shown by the thermometer *X*. Every necessary precaution being now taken to observe the level of the surfaces of the mercury in the two branches, air was forced into the vessel by the pump, which caused the mercury to rise in both the open long tube *d d*, and in the close tube *a a*, and thus the compression and elasticity of the same volume of enclosed air was ascertained, as given in the following Table, for three distinct series of experiments, and for different pressures varying from one to twenty-seven atmospheres.

The preceding results are no otherwise connected with our present inquiry than as they served in the subsequent experiments to furnish a measure of the degrees of pressure due to the different degrees of temperature of the steam. At the same time, they are interesting in proving that the law first pointed out by Mariotte, (that the space into which air and other elastic fluids are compressed is inversely as the pressure,) is true as far as these experiments extend, viz. to twenty-seven atmospheres; whereas it had been supposed to have begun to fail under much less pressures.

(136.) In the second division of the experiments the long tube was removed, and the passage stopped, while the forcing pump was replaced by a steam pipe from a powerful steam boiler; the same air was preserved in the close tube, and the pressure of the steam was now ascertained by the compression of the air according to the scale obtained in the preceding experiments. The experiments were carried as far as to a pressure of twenty-four atmospheres, or to 18 metres of mercury, as in the following Table. The two columns marked great and small thermometer indicate the reading of a long and short thermometer immersed, the one some depth in the water of the boiler, and the other in the steam above the water. The last column but one indicates the state of the thermometer at the time of observation; the letters *a*, or *a, l*, expressing that the mercury was ascending, or ascending slowly; *p* that it was ascending quickly; *max.* the maximum.

(137.) Deduction of formulæ expressing the relation between temperature and elasticity.

On casting one's eye over the preceding Tables we

Machinery.

Manufactures. shall find a tolerable accordance in the results of the different experiments, but such an extremely apparent irregularity between the temperatures and elasticities, as almost to discourage one from attempting to obtain a formula that shall express the relations between them. Numerous attempts, however, of this kind have been made by different Mathematicians and Philosophers, some of which it will be well to examine and compare in this place.

By Dalton. Dalton inferred from the experiments which he made, that the relation between the temperature and elasticity was such, that while the former increased in an arithmetical progression, the latter increased in a geometrical progression, or very nearly.

By Ure. Prony, Laplace, Biot, and Ivory, have each given formulæ for expressing this relation, but they have been found generally defective in the higher pressures. Dr. Ure proposed not a formula but a sort of principle of interpolation, which agrees pretty well with minor pressures, viz. beginning at the temperature 212° of Fahrenheit, at which the pressure or elastic force is 30 inches. To find it for 222°, he directs to multiply 30 by 1.23, for 232°, multiply the elastic force of 222° by 1.22, &c. always for the next 10° higher, multiplying the preceding pressure by the last multiplier reduced by 1, in the hundreds place of decimals. Below 212°, the pressure is obtained in a similar way for every tenth degree, the first by dividing by 1.24, then for the next 10° by 1.25, 1.26, &c.

This, however, must necessarily fail after the addition of 230°, because after this the elastic forces would by this rule decrease, which is not likely to be the case.

By M. Roche. M. Roche, Professor of Mathematics at Toulon, proposed the following formula :

$$f = 760 \times 10^{\frac{m t}{11 + 0.03 t}};$$

where f is the elastic force of the steam in millimetres of mercury, t the temperature in degrees of the Centigrade thermometer, reckoned from 100°, positive above and negative below, and m a mean coefficient to be determined by experiment. This value, from a comparison of the preceding experiments, is $m = 0.1645$, which, being substituted for m , and the equation expressed in terms of t , it becomes

$$t = \frac{11 (\log. f - \log. 760)}{0.1644 - 0.03 (\log. f - \log. 760)}.$$

This is nearly the only formula of the exponential kind which approximates towards the truth for high temperatures; it would be useless, therefore, to give them. Most others are of the general forms

$$f = \left(\frac{t \pm a}{q} \right)^n \text{ or } t \pm a = q^n \sqrt[n]{f};$$

where t denotes the temperature, $\frac{1}{n}$, an index to some root

of f , the elastic force, and q and a numbers to be determined by experiment. That is, they all suppose the temperature to commence from some certain point, where the elasticity of the vapour is zero, and then assume that, for any number of degrees above this point, the elasticity is proportional to some power of these.

Thus Mr. Tredgold obtains

$$f = \left(\frac{t + 75^\circ}{85} \right)^6 \text{ or } t = 85 \sqrt[6]{f - 75^\circ};$$

in which t is the temperature on the Centigrade thermometer, and f centimetres of mercury. M. Coriolis obtains

$$f = \left(\frac{0.01878 t + 1}{2.878} \right)^{5.335} \text{ or } t = \frac{2.878 \sqrt[5.335]{f - 1}}{0.01878};$$

where t are Centigrade degrees as above, but f is expressed in atmospheres of 0.76 metres of mercury.

MM. Prony, Arago, &c., in the *Exposé* above referred to, have

$$f = (0.7153 t + 1)^5 \text{ or } t = \frac{\sqrt[5]{f - 1}}{0.7153};$$

where t are the degrees above 100°, and 1 is taken to represent an interval of 100°.

The following Table exhibits a comparison of these four formulæ for different pressures, varying from two to twenty-four atmospheres.

TABLE exhibiting the Approximations of the Elastic Force of Steam, and the corresponding Temperatures, by four different Formulæ.

No of Observations.	Elasticities in metres of Mercury at 0°.	Elasticities in Atmospheres of 0.76 metres.	Observed Temperatures, Centigrade.	Temperatures by Tredgold's formula.	Temperatures by the formula of De Roche.	Temperatures by the formula of Coriolis.	Temperatures by formula of the <i>Exposé</i> .
1	1.62916	2.14	123.7	123.54	123.58	123.45	122.97
3	2.1816	2.8705	133.3	133.54	133.43	133.34	132.9
5	3.4759	4.5735	149.7	150.39	150.23	150.3	149.77
8	4.9383	6.4977	163.4	164.06	163.9	164.0	163.47
9	5.6054	7.3755	168.5	169.07	169.09	169.3	168.7
15	8.840	11.632	188.5	188.44	188.63	189.02	188.6
21	13.061	17.185	206.8	206.15	207.04	207.43	207.2
22	13.137	17.285	207.4	206.3	206.94	207.68	207.5
25	14.0634	18.504	210.5	209.55	210.3	211.06	210.8
28	16.3816	21.555	218.4	216.29	218.01	218.66	218.5
30	18.1894	23.934	224.15	222.19	233.4	224.0	224.02

The agreement in all these four cases is very remarkable, considering that they were all, except the last, found from experiments which did not exceed six atmospheres. It is indeed obvious from these, that the elastic power of steam increases very nearly as the fifth or sixth power of the temperature, the latter commencing from some point below the zero; but this exact point and the exact power remains still to be determined.

We shall conclude this part, on the elasticity of steam in contact with water, with the following Table; in which from 1 to 4 atmospheres are computed by Tredgold's formula, and from 4 to 50 by the formula given in the *Exposé*. As far as 8 atmospheres, the computation is made for every half atmosphere, from 8 to 24 for every atmosphere, and from 25 to 50 for every 5 atmospheres. It is proper to observe that Mr. Tredgold's formula agrees very well for pressures that are less than one atmosphere, which is not the case with the formula given by MM. Prony and Arago.

Manufactures.

(138.) Of the Specific Gravity of Steam in contact with Water at different Degrees of Temperature.

Density of steam at different temperatures.

The amount of latent heat, or the quantity of heat absorbed in the conversion of water at 212° into steam, and the elasticity of steam at various temperatures, have been treated of in the preceding pages; we have now to show the density of steam at various temperatures and pressures, which is very necessary to be known for various objects, and particularly in the process of condensation; in order properly to proportion the capacity of the condenser for different quantities of steam. It appears from the experiments of Mr. Dalton, that the weight of a cubic foot of steam at 212° is 253 grains; others give it as 254.7 grains. Now a cubic foot of water weighs 62½ pounds, each pound containing 7000 grains,

therefore $\frac{62\frac{1}{2} \times 7000}{254.7} = 1711$, the number of volumes

which a given volume of water occupies in the form of steam at 212°.

Now assuming the density of steam in contact with its water of generation to be proportional to its elastic force, we have, as thirty inches of mercury, the pressure at 212°, is to the elasticity at any other temperature, so is 254.7 the grains of aqueous vapours in the former case to that in the latter. In this way the following Table has been computed.

TABLE showing the Pressure, Specific Gravity of Steam, and Weight of a Cubic Foot at different Temperatures.

Pressure in inches of Mercury.	Temperature Fahrenheit therm.	Weight of Cubic foot in grains.	Specific gravity, air being unity.	Pressure in inches of Mercury.	Temperature Fahrenheit therm.	Weight of Cubic foot in grains.	Specific gravity, air being unity.

(139.) Of the Elastic Force of Steam when not in contact with its Water of Generation.

In all that has preceded, the steam has been supposed in contact with its water of generation, and of the same temperature with it, in which case both the increased density of the steam, and its increased elasticity from heat, contribute to increase its elastic force; but when steam is cut off from its generating water, an increase of temperature does not increase its density, but merely its elastic force, the density remaining constant; and, therefore, the laws of its increasing force are altogether different from the former, and much more simple and easier to express and comprehend.

It has been well ascertained that an elastic vapour, steam for example, in having its temperature raised from the temperature 0° on Fahrenheit's scale, is expanded $\frac{1}{459}$ th part for every degree on that scale.

Let v denote the volume a given quantity of steam occupies at 0°, then the volume at t degrees will be

$$v' = v + \frac{t v}{459},$$

and at t' degrees $v'' = v + \frac{t' v}{459}$

By the first equation we obtain

$$v = \frac{459 v'}{459 + t}.$$

Substituting this value of v in the second equation,

$$v'' = v \times \frac{459 + t'}{459 + t}.$$

Whence the volume of steam v , being given for any temperature t , the volume v'' it would occupy, the pressure remaining the same, may be found by the above formula; or in words,—

To the temperature before and after expansion add 459; divide the greater number by the less, and multiply the quotient by the volume before expansion, and the product will be the volume due to the higher temperature.

Or divide the lesser number by the greater, and multiply the quotient by the volume at the higher temperature, and the product will give the volume at the lower.

We here suppose the pressure to remain the same; but if the volume remain the same, then the elastic force

Manufactures. will be increased in the same proportions as the volumes would be under a constant pressure.

If, therefore, f denotes the elastic force at the temperature t ,

$$f' = f \times \frac{459 + t'}{459 + t}$$

will be the elastic force at the temperature t' , the space remaining constant.

By means of these formulæ we may readily find the volume a given measure of water would occupy in steam of any given elasticity and temperature. It has been seen, for example, that a cubic foot of steam at 212° contains 254.7 grains of vapour, and that it occupies 1711 times the space these grains in the form of water would occupy at 60° , and that the pressure of the steam at 212° is 30 inches of mercury.

Now the space a cubic foot of steam would occupy at the temperature t' is by the formula,

$$v = 1711 \times \frac{459 + t'}{459 + 212} = 2.55 (459 + t');$$

whence again by the second formula, f being in this case 30 inches, we have

$$f' = 30 \times 2.55 (459 + t') = 76.5 (459 + t').$$

That is, to the given temperature add 459, and multiply the sum by 76.5, which will give the elastic force, the volume remaining the same. This being again divided by the inches of mercury due to the pressure, will give the number of volumes a given volume of water would occupy at the proposed temperature and pressure.

By these means the following Table has been computed, showing the number of cubic feet one cubic foot of water would occupy at the different pressures and temperature stated therein.

TABLE showing the Number of Cubic Feet of Steam which may be formed by one Cubic Foot of Water, at different Temperatures and Pressures.

(140.) *On the Velocity with which Steam rushes into a Vacuum or into a Fluid of greater Rarity than itself.*

The method of computation in this case is precisely the same as has been explained in the article PNEUMATICS; that is, we must, after knowing the temperature of the steam and its pressure, compute the height of a uniform atmosphere which would produce the same pressure; then the velocity which a heavy body would acquire in falling through this height is the velocity with which the steam would rush into vacuo. And if the question

be the velocity with which it would rush into another fluid of greater rarity than itself, then find the height of a uniform atmosphere equal to the difference of pressure, and the velocity a heavy body would acquire in falling through this height will be the velocity sought. This, however, supposes that the steam experiences no resistance in its motion, but that the aperture is open and the passage made in a right line; and in this case it being the height of the atmosphere, we shall have the velocity

$$v = 8 \sqrt{h}.$$

But it is said that in consequence of the bendings and other hinderances which the steam encounters in passing along pipes, that the multiple 8 must be reduced to $6\frac{1}{2}$, 6, or 5, according to circumstances; and as it is difficult to form a correct judgment as to the amount of this reduction, it is obvious that but little practical good can be derived from such investigations. It will be seen, however, that, even with the smaller multipliers, the velocity is so great that the relative speed of the piston is very inconsiderable, and may be rejected in estimating the effect of the steam upon it, as we have already remarked. (Art. 25.)

This velocity, if we had the means of making a proper estimate of the retardations, that is, if we could arrive at its actual practical amount, might be advantageously employed to ascertain the proper dimensions of steam pipes, passages, and valves; but we apprehend that these can never be computed theoretically. Experience here is our only guide, and this seems to point out that in low-pressure engines the passages ought to be in diameter about $\frac{1}{3}$ th the diameter of the piston, and consequently the area about $\frac{1}{9}$ th; others reckon about an inch per horse for the area of the passages, which does not differ greatly from the above dimensions.

(141.) *Of the Quantity of Fuel requisite to produce a given Quantity of Steam; and on its Efficiency as a Mechanical Agent.*

In the preceding sections have been stated all the more important properties of steam; it will be proper in this place to offer a few remarks and experimental results relative to the power of different kinds of fuel. The effect produced from a certain weight of fuel depends of course upon the perfection of the combustion; it is necessary, therefore, before any comparison can be formed, to be assured that the different experiments have all been conducted on the best principles of producing combustion; this may throw some doubts on the following results, at the same time the celebrity of the authors must assure us that they are not very erroneous.

The trials of the quantity of steam a given quantity of fuel will produce, are by no means so numerous as might be expected by those who are unacquainted with the difficulty of ascertaining the results with precision. A practical man shrinks from the task of making accurate trials, either in consequence of the great degree of attention and labour they require, or of the expense attending the process; merely theoretical men have not the means; and it would appear that those who may be supposed to have both time and means at command, too often want the disposition.

The following are amongst the best results we can quote relative to this inquiry.

Quantity and efficiency of fuel.

Manufactures. TABLE showing the Quantity of Heat produceable from different Kinds of Fuel.

Different kinds of Fuel experimented on.	Pounds of Water heated 1° by 1 pound of Fuel.	Pounds of Water at 52° converted into Steam at 220°.	Pounds of Fuel to transform a cubic foot of Water 52° into Steam 220°.

	4175	3.56	17.5

Efficiency of fuel in the production of steam and steam power.

Sleek or refuse small coal produces about three-fourths of the effect of good coal of the same species.

(142.) *Of the efficiency of a given quantity of fuel.*—Unfortunately there appears from the preceding Table to be great uncertainty in the result obtainable from a certain weight of fuel. Mr. Watt's results vary between the limits 6.9 and 10.4 in estimating the quantity of water raised one degree of temperature by a given weight of coal, and between the limits 10½ and 7 in estimating the weight of coals requisite to convert a cubic foot of water into steam; and we cannot, therefore, from these expect to arrive at any very definite result in the estimation of the efficiency of fuel in general. Without referring, then, to the preceding results, which may be said to be obtained from experiments comparatively on a small scale, we shall, in the following estimate, adopt the numbers of Mr. Davies Gilbert, which appear to be drawn from observations on a very large scale. There is certainly no place in the world in which the production of steam is so well understood as in the mining district of Cornwall, no place in which a given weight of coal is rendered so efficient; and, we may add, that there are few men, if there be any one, who has a better theoretical knowledge of steam and the steam-engine than the gentleman above named, whose situation as President of the Cornwall Geological Society affords him the means of acquiring the best information on these subjects. Mr. Gilbert, in a paper read before the Royal Society in 1827, enters into this question, that is, the relation which subsists between the quantity of fuel consumed and the effect produced in different engines, from the actual practical results of the different mine engines in the above district. In order to estimate the efficiency of steam acting uniformly with its entire force, at a power corresponding to 30 inches of mercury in reference to the consumption of one bushel of coals, weighing at a medium 84 pounds, he assumes from the mean of repeated experiments, which agrees, however, nearly with the minimum of Mr. Watt's experiments in the preceding Table, that seven pounds of coals will convert one cubic foot of water into steam, or that one bushel of coals will convert 14 cubic feet of water from the mean temperature into steam. His estimate of the

quantity of space a given quantity of water occupies in the form of steam, is less also than has been stated in the preceding pages of this Chapter: he considers it to occupy only 1330 times the original bulk, whereas it is computed (Art. 133.) from Dalton's experiments to occupy 1711 times. Taking, however, Mr. Gilbert's number, 14 cubic feet of water multiplied by 1330 gives 18,620 cubic feet occupied by the steam producible from one bushel of coal; this occupied with water would be $18,620 \times 62\frac{1}{2} = 1,150,410$ pounds; and as 30 inches' pressure of mercury is equal to 33.92 feet of water, it appears that, the vacuum being produced, one bushel of coal is sufficient to raise 1,150,410 pounds to a height of 33.92 feet, or 39,361,000 pounds a foot high; and if, instead of considering them to occupy only 1330 times the bulk of water, we take Mr. Dalton's number, 1711, there would result,

$$\frac{39,361,000 \times 1711}{1330} = 50,607,000 \text{ pounds}$$

one foot high for the efficiency of one bushel of coals; so that on this estimate we may state in round numbers, that one bushel of coals is competent to raising 50,000,000 pounds one foot high. The estimated horsepower, we have seen, will raise 33,000 pounds one foot high in a minute, or $33,000 \times 60 = 1,980,000$ pounds in an hour; hence a bushel of coals is equivalent to the performance of a horse for about 20 hours on the former estimate, and for more than 25 hours on the latter. Taking the least, it appears that the consumption of 4.1 pounds of coals will produce the mechanical effect of one horse for an hour. This, however, supposes every thing in the abstract, that the vacuum is produced, and the water forced up without friction or impediments of any kind; but in small engines where the friction is considerable, and other impediments are to be overcome, it is generally found that from 7 to 10 pounds of coals are required to perform the estimated duty of a horse for an hour; which estimate has been adopted in Art. 2. in comparing the effect of different first movers.

Seeing, then, that from 40,000,000 to 50,000,000 is the full efficiency of one bushel of coals, it will be considered extraordinary that, through the intervention of an engine, and the skill and ingenuity of man, this natural efficiency of steam may be, and is actually made to produce double the above effect. In illustrating this mystery we shall quote Mr. Gilbert's own words. After stating the efficiency of steam as above, and explaining that every impediment is supposed to be removed, he proceeds to say, that when this power of steam is applied through the medium of a piston acting in a cylinder of a steam engine, large deductions must be made to arrive at the practical duty, that is, of the weight actually raised.

The air pump is usually constructed of a size to require about one-eighth part of the efficiency.

Some imperfection in the vacuum cannot be avoided, and friction must exist to a considerable amount where bodies in motion have to confine an elastic vapour ready to escape through the smallest aperture, so that probably 30,000,000 would have exceeded the attainable limit of duty, but for two expedients, viz.

First, by causing the steam to act expansively after exerting its whole force through a certain part of the cylinder; and,

Secondly, by raising the temperature much above 212°

Machinery.

Natural efficiency increased by artificial means.

First, by working expansively.

Manufactures. of Fahrenheit, and thereby communicating to the steam a power beyond what is termed atmospheric strength. This, of course, requires more fuel, but not proportional to the increase of force.

To illustrate the first of these properties. Let AB, fig. 9, represent the portion of the cylinder through which the piston is urged by the entire force of the steam, and let its force be expressed by unity; and let the supply of steam from the boiler be cut off by the valve at r , when the piston has descended to B. Assume further that the piston has descended through the space x to B', urged by the expansive power or elasticity of the steam, the density of which will then be $\frac{1}{1+x}$; and assuming that densities and elasticities are

proportionate, $\frac{x'}{1+x}$ will be the fluxion of the efficiency,

and the efficiency itself equal to the fluent of this or to the nat. log. of $(1+x)$, and the efficiency of the whole stroke from A to B is, therefore, $1 + \text{nat. log. } (1+x)$, giving this very curious result, (*Phil. Trans.*) that when x is infinite, the efficiency is also infinite, or exceeding any assignable limit. When

$n = 1$ or the steam is shut off at a half stroke.	efficiency = 1.693
$n = 2$ or at one-third.	= 2.099
$n = 3$ or at one-fourth.	= 2.356
$n = 4$ or at one-fifth.	= 2.609
$n = 5$ or at one-sixth.	= 2.792

And to the latter extent, viz. $n = 5$, the principle has been attempted; but beyond this, notwithstanding the theoretical expression, it is not likely any practical advantage could be obtained, if it can be to this extent.

Mr. Gilbert, in stating these results, observes that several important circumstances are necessarily omitted in the investigation; namely:

1. The reduction of temperature, and, consequently, of elasticity, caused by rarefaction as the steam expands.
2. The increased relative effect occasioned by the reaction of the imperfect vacuum.
3. The increased relative burden of the air pump.
4. The relative increased friction.

So that, although this mode of working is highly advantageous, yet it is probable that, in practice, not more than from one-half to two-thirds of the cylinder can beneficially be occupied by expansive steam.

(143.) The second expedient, that of employing steam at a high degree of temperature, and, consequently, of pressure, would naturally suggest itself from the facts recorded in some preceding articles in this Chapter; namely, that a quantity of heat amounting to about 900 times that required to raise the temperature of a given weight of water one degree on Fahrenheit's thermometer, becomes latent in the conversion of that water into steam; and that an elevation of temperature of 40° of Fahrenheit above 212° , double the steam's elasticity, that 30° more treble it, and so on, see Table, Art. 125. And hence it would seem to follow that an increase of efficiency might be obtained almost ad libitum, by increasing the temperature of the steam; but in this reckoning the following most important circumstances were overlooked, till experience forced them into view: That the temperature of steam cannot be raised with a speed suitable to mechanical purposes in any other way than in contact with its water of generation; and that water heated above 212° sends off more steam,

Machinery. with a proportionate absorption of latent heat, increasing the density of the steam previously generated of atmospheric elasticity, so as about to double its power at 256° , but at an expense of fuel not much inferior to the power gained.

There is, however, a gain by adopting this principle of heating beyond 212° , and there is a gain by making the steam act expansively; and these are carried in the Cornish engines to a very considerable extent. We have seen that the natural efficiency of steam is from 40,000,000 to 50,000,000 of pounds raised a foot high with every impediment removed; and in many Cornish engines the working duty, after overcoming all impediments, amounts to 60,000,000, 70,000,000, and 80,000,000, and in one engine in particular, the duty effected by it for several days was 102,000,000, which is from two to two and a half times its natural efficiency.

(144.) *Condensation of steam.*—We have hitherto spoken of the generation of steam, its density, elasticity, and power of expansion, but another of its important properties remains to be described and investigated, its capability of rapid condensation. It has been already observed, that if the condensation of steam required as much time as its generation, or any very considerable time, its efficiency as a mechanical agent would be very inconsiderable; this was the defect with the Marquis of Worcester's, Morland's, and some other early engines; in fact, its capability of rapid condensation was not then understood, and the steam engine, in comparison with what it now is, may be said to have been powerless. When a substance colder than steam itself is put in contact with it, the steam condenses till the temperature of the cold body becomes the same as that of the steam, or till the whole mass of steam is condensed to a degree of elasticity corresponding to the temperature to which the cold body is raised by the heat of the steam, it being one of the properties of heat, already stated in the definitions, to restore itself to equilibrium; consequently, the colder the body is, or its temperature being the same, the greater its surface, the more rapidly the temperature of the hot body will be reduced, and in the case of steam, the more rapid its condensation. Consequently, in this process in a steam engine, the surface of the body through which the condensation is made should be as great, and its temperature as low as possible. Another quality the condensing body ought to possess, is that of being a good conductor of heat, whereby the process of condensation may be as rapid as possible. It may be readily demonstrated that if steam were to condense so as to lose only equal quantities of heat in equal times, and, of course, equal degrees of elastic force, half its power would be lost.

Water is a body particularly effective for this purpose: it may generally be obtained at a medium temperature; it is an excellent conductor of heat; it has great specific heat; and in the form of a jet may be made to present a very great cooling surface to the steam. The discovery of this effect of water, Savery states, was by an accident, while making some experiments with a Florence flask. This, however, is denied by Desaguliers, who says the discovery was made accidentally by Newcomen, with one of his early engines, by a little water having found its way through the piston into the receiver of the cylinder which produced a sudden and most extraordinary effect. However this may be, it is the capability of steam for rapid condensation on which depends the immense power of the steam engine.

Manufac-
tures.

It will be seen, however, in the following Chapter, that although water thus furnishes an excellent medium for the production of this effect, it is, like most other conveniences, attended with its inconveniences. All the water used for injection has to be again removed from the condenser; this water also brings in with it a certain portion of atmospheric air which must also be removed; and to effect these objects, an air pump, requiring considerable force, must be employed, which is a deduction of so much useful effect: moreover, in many cases a sufficient quantity of water for the purpose cannot be obtained, or not without considerable inconvenience.

This has led many ingenious men to endeavour to produce condensation without the injecting water, but hitherto with little success. A patent has, however, been lately obtained by Mr. Hall, of Basford, near Nottingham, which is said to have been tried with great success in several new engines, this is by exposing the steam to a great extent of pipes filled with water, or in which water is constantly passing, and which is said to produce the desired effect. By this means the condensed steam in the form of water is returned to the boiler, the steam regenerated and condensed always employing the same water, which (supposing even some waste in the process) must still be acknowledged is a great advantage. A somewhat similar contrivance, at least one for the same purpose, has been also recently proposed by Mr. Howard, jun., of the King and Queen Iron Works at Rotherhithe, in the patent for a steam engine without a boiler, described in a subsequent article.

Whatever success, however, may ultimately attend these engines, the process of condensing by injection will be practised to a great extent, and it will, therefore, be desirable to give a concise investigation of the circumstances which occur in this process.

Let W denote the weight of water used for injection, its temperature being t , and let T denote the temperature of the steam, its weight being w ; let also x be the temperature of the water after condensation. Then taking 1000° as the latent heat of steam.

$W(x - t)$ will be heat gained by the water, and $w(1000 + T - x)$ will be the heat given out by the steam; and as these must be equal, we have

$$W(x - t) = w(1000 + T - x).$$

Whence

$$W = \frac{w(1000 + T - x)}{x - t},$$

and

$$x = \frac{w(1000 + T + wt)}{W + w}.$$

To find the quantity of water necessary to produce condensation, the admitted temperature of the water in the condenser after condensation must be fixed; it is not easy to carry this lower than 100° : in low pressure engines the temperature of the steam is generally about 220° , and that of the injected water may be taken at 52° . Whence $x = 100^\circ$, $T = 220^\circ$, $t = 52^\circ$, wherefore

$$W = \frac{w(1000 + T - x)}{x - t} \text{ becomes}$$

$$W = \frac{w(1000 + 220 - 100)}{100 - 52} = 23\frac{1}{2}w.$$

So that to obtain the temperature of the water in the condenser at 100° , the quantity of injection water must be between twenty-three and twenty-four times as much

as the quantity of water requisite to fill the cylinder with steam at 220° . Now we have seen that a cubic inch of water will make about a cubic foot of steam of this elasticity or temperature, and therefore $23\frac{1}{2}$ inches will be required for every cubic foot of steam in the cylinder. According to Mr. Watt's practice he allowed a pint or $28\frac{7}{8}$ inch for this purpose.

In low pressure engines the temperature $T = 220^\circ$ is pretty constant, and $t = 52^\circ$ may also be supposed a fair medium temperature for the injection water; and substituting these as constants we shall have the ratio of W and w more simply expressed by

$$W = \frac{w(1220 - x)}{x - 52}.$$

Where by merely inserting different values of x , or different temperatures for the condensed water, we may obtain the ratio between W and w for all temperatures; and the capacity of the cylinder and quantity of condensing water being given, we, of course, readily obtain the quantity in question.

Thus, when the temperatures of the condensed water are as below, the ratio of W to w will be also as there expressed, viz.

$x = 100^\circ$	$W : w :: 23.3 : 1$
$x = 110^\circ$	$W : w :: 19.9 : 1$
$x = 120^\circ$	$W : w :: 16.3 : 1$
$x = 130^\circ$	$W : w :: 13.9 : 1$
$x = 140^\circ$	$W : w :: 12.7 : 1$
$x = 150^\circ$	$W : w :: 10.9 : 1$
$x = 160^\circ$	$W : w :: 9.8 : 1$
$x = 170^\circ$	$W : w :: 8.0 : 1$

And in like manner the proportions may be obtained for all temperatures. It appears, therefore, that the higher the temperature of the water in the condenser, the less injection water is required; but the elasticity of the steam in the condenser increases so rapidly, that it is highly desirable to reduce the water to the lowest possible temperature, when a sufficient quantity of cold water can be obtained. The more water is used, however, the larger the condenser must be, and the greater the power required to work the air pump, so that practical men here, as in most other cases, must be limited in their proportions according to circumstances. The most usual temperature aimed at is 100° , at which the elasticity of the steam is about equal to 2.08 inches of mercury.

Early History of the Steam Engine.

1st Period to 1769.

(145.) A knowledge of the expansive power of steam could not long have remained hidden from mankind after they had acquired the art of applying fire to culinary purposes, but it was probably a long time afterwards before the thought occurred of applying it to produce motion. The first indication we find of such an idea is by Hero of Alexandria, who described a contrivance for effecting this object, and of which he is generally considered the inventor.

This consisted of a caldron in which steam was generated by a concealed furnace; out of the former proceeded two arms, one hollow or tubular, the other solid; they ascended above the boiler and were there bent inwards, and between them was suspended, as on an axis, a hollow globe. The hollow tube or pipe being connected

Hero's application of steam to produce motion.

Manufac-
tures.

with the globe by a steam-tight joint, but still such as to admit freedom of motion; and the opposite side of the globe was connected with the fixed solid arm so as to admit of the free rotation of the ball. From the latter proceeded two short tubes bent at right angles with the axis, and opposite to each other in direction, from which the steam, generated in the boiler, and transferred to the globe, escaped, and by the resistance the vapour encountered from the atmosphere, the ball was put in rapid rotation.

Brancas's
proposition.

Early in the XVIIth Century, *i. e.* in 1629, another contrivance was published by an Italian Philosopher, Brancas. This, like the former, depended upon the elastic power of steam. It consisted of a close vessel of copper, representing the head of a negro filled with water. It was furnished with a small tube proceeding from the mouth, and seemed to be intended to give motion to a sort of wheel, which was impelled by the action of the steam or elastic vapour generated within. The Work in which this engine was first described, was published in 1629; it is exceedingly rare, but a fac simile of the engraving is given by Partington in his descriptive account of the steam engine, from an engraving in the possession of Colonel Colby of the Royal engineers.

These futile attempts for the production of motion and power by the operation of steam would scarcely deserve any attention, but that the importance of the present engine renders highly interesting every step, however remote, which appears to have in any respect contributed to the general march of invention in the progress of this noble Machine. The motions above described were most probably, in their effects, very little more than those which we are now enabled to produce by our electrical Machines, galvanic batteries, and magneto-electric apparatus, the origin or cause of the motion not being very dissimilar; *viz.*, the resistance offered by the air to the escape of a highly elastic fluid.

(146.) The expansive force of steam is doubtless one of the great principles on which the power of the steam engine as a mechanical agent depends, but a still greater, and without which the former would be of little avail, is its property of rapid condensation. If the progress of condensation were as slow as that by which its expansive power is developed, its mechanical efficiency would be very small; it was the discovery, therefore, of this property which must be considered as the first step towards the invention of the present steam engine. Some persons have thought that this discovery was made by the Marquis of Worcester, about the middle of the XVIIth Century, but it has been maintained with more reason that this author was only acquainted with the expanding power, and that nothing further is implied in his obscure remarks in his celebrated Work, *A Century of the Names and Scantlings of Inventions*, published without date at the time above referred to. The author died in 1663.

Marquis of
Worcester's
project of a
steam en-
gine.

Nothing can be more obscure and unintelligible than the notice which this mysterious writer has left of his invention, yet there can be no doubt he had obtained some extraordinary results by the power of steam, whether he availed himself of the condensing power or not. At all events, had he published what he had invented for the benefit of mankind, instead of enveloping the whole in mystery, for the purposes of personal vanity, he would have been entitled to the respect and veneration of his Country.

It is said that this nobleman, while confined in the Tower of London, was preparing some food on the fire

VOL. VII.

of his apartment, and the cover of the vessel having been closely fitted, was, by the expansion of the steam, suddenly forced off and driven up the chimney. This circumstance attracting his attention, led him to a train of thought, which terminated in this important discovery. But no figure has been preserved of his invention, nor, as we have good reason to suppose, any description of the Machine he employed, except what is given in the sixty-eighth article in the above-mentioned Work. We shall content ourselves, therefore, with extracting that article from the author's MS. preserved in the British Museum.

Machinery.

"An admirable and most forcible way to drive up water by fire; not by drawing or sucking it upwards, for that must be, as the Philosophers call it, *infra sphæram activitatis*, which is but at such a distance. But this way hath no boundary, if the vessels be strong enough; for I have taken a piece of a whole cannon, whereof the end was burst, and filled it three-quarters full of water, stopping and screwing up the broken end, as also the touch-hole; and making a constant fire under it, within twenty-four hours it burst and made a great crack; so that having found a way to make my vessels, so that they are strengthened by the force within them, and the one to fill after the other, I have seen the water run like a constant fountain stream, forty feet high: one vessel of water rarefied by fire driveth up forty of cold water. And a man that tends the work is but to turn two cocks, that one vessel of water being consumed, another begins to force and refill with cold water, and so successively, the fire being tended and kept constant, which the self-same person may likewise abundantly perform in the interim between the necessity of turning the said cocks." *Vide Harleian MSS.*, No. 2428.

(147.) We have said, speaking of this invention, that some have supposed that the Marquis of Worcester availed himself of the contracting property of steam; Mr. Tredgold, however, is not willing to admit that he possessed any knowledge of this principle, and has given a sort of engine such as he conceived might resemble the one indicated in the noble author's description. Tredgold says, p. 3. of his *Treatise on the Steam Engine*, This description puts it beyond a doubt, that the Marquis of Worcester knew that steam, heated in a close vessel, acquires an immense degree of force, and that this force could be effectively applied to raise water. The effect of condensation he does not appear to have been at all acquainted with, and, therefore, this mode of operation must have been exceedingly simple, and, probably, of the nature exhibited in pl. ix. fig. 6, where B is the boiler, C one of the vessels with a pipe to deliver the water to an elevated cistern D.

Probable
form of the
Marquis of
Worcester's
engine.

Pl. ix.
Fig. 6.

Now suppose the vessel C to be supplied from a cistern of cold water by a pipe, so that it would be filled on opening the cock E, and this cock being closed; if, when the steam in the boiler is of sufficient strength, the cock F be opened, the pressure of the steam on the water in C would cause it to ascend from C, through the pipe *a*, into the cistern D. The vessel C being emptied, and the cock F being shut, it would refill with water on opening the cock E. Another vessel C, and its cocks and pipes, are necessary to complete the species of water engine indicated by the description, which may be conceived to be on the other side of the boiler.

Such a mode of raising water would be most expensive from the quantity of condensation when the steam came in contact with cold water; but it was fully capable of producing the quantity of effect mentioned, for it is

v

Manufac-
tures.

only equivalent to raising twenty cubic feet of water, or 1250 pounds, one foot high by one pound of coal, or about the 200th part of the effect of a good steam engine. Hence it appears that to the Marquis of Worcester must be ascribed the first invention and trial of a practical mode of employing steam as a prime mover, and of applying it to one of those great purposes for which it has been so useful to society.

(148.) In 1683, a scheme for raising water by the agency of steam was offered to the notice of Louis XV. by an ingenious English mechanic, Sir Samuel Morland. He was presented to the French Monarch in 1682, and in the course of the following year his apparatus is said to have been actually exhibited at St. Germain. The only notice of this plan occurs in the collection of MSS. to which we have already alluded, and forms the latter part of a very beautiful volume, containing about thirty-eight pages, and entitled *Elévation des Eaux par toute Sorte de Machines, réduite à la Mesure, au Poids, et à la Balance. Présentée à sa Majesté très-Chrétienne par le Chevalier Morland, Gentilhomme Ordinaire de la Chambre privée, et Maître des Mécaniques du Roy de la Grande Brétaigne*, 1683.

Morland's
steam en-
gine

The MS. is written upon vellum, richly illuminated, and the part which has reference to the steam engine occupies only four pages, commencing with a separate title, &c. It is also accompanied by a Table of the sizes of cylinders, and the account of water to be raised by a given force of steam. This curious Memoir forms an important link in the chain of historical evidence, we shall, therefore, offer no apology for presenting a translation of it to the notice of the reader.

"*The Principles of the new Power of Fire, invented by Chevalier Morland in the Year 1682, and presented to his Most Christian Majesty 1682.*"

"Water being evaporated by the force of fire, the vapour shortly acquires a greater space (near two thousand times) than the water, occupied before; and was it to be always confined, would burst a piece of cannon. But being well regulated according to the laws of gravity, and reduced by Science to measure, weight, and balance, then they carry their burdens peaceably, (like good horses,) and thus become of great use to mankind, particularly for the elevation of water, according to the following Table, which marks the number of pounds that may be raised 1800 times per hour by cylinders half full of water, as well as the different diameters and depths of the said cylinders."

(149.) In 1698, three years after Sir Samuel Morland died, Dr. Papin, a Frenchman, suggested the idea of employing the expansion and condensation of steam to form a partial vacuum under a piston for raising water; and if, therefore, the condensation did not form any part of the last two schemes, we must admit that this author made an important step towards the present engine. In this contrivance, the pressure of the atmosphere on the upper side of the piston formed the moving power; but the arrangement proposed was impracticable, as the fire was to be alternately applied to and removed from the cylinder, and the expansion of it by heat was to raise the piston, and its contraction by cooling, when the fire was removed, was to cause a partial vacuum, and, consequently, the descent of the piston was to be produced by the pressure of the atmosphere. Here, at least, we have an intelligible process; for although it seems doubtful whether, according to this plan, any useful effect could have been produced, yet the principle of the atmospheric engine is here clearly indicated; and the step between this and the next proposition by Savery, was by no means difficult.

(150.) In 1699, M. Amontons published a description of a Machine, which he called a *fire-wheel*, designed to be moved by the spring of air when expanded by heat, and afterwards condensed by contact with cold water. The continual access of heated air to water would ultimately render the air saturated with vapour; but even then it would not be more than an air engine, and a very indifferent one, being exceedingly complex. In this wheel, one part of the circumference was exposed to the heat of the furnace, and the other to a stream or current of cold water; and by means of close buckets communicating with each other, which were placed round the circumference, the steam produced into the bucket on one side of the wheel drove the water into the buckets on the other side; so that one side of the wheel was always much heavier than the other, and must, therefore, turn round, and thus be made to execute some work. It is very doubtful, from the complicated nature of this Machine, whether, if the author had lived, it could ever have been made available to any useful purpose: at all events, his death caused it to be wholly neglected, and this was also the case with another construction of about this date, by M. Deflander, who also presented a steam

Fire wheels
by Amon-
tons and
Deflander.

Manufactures. wheel to the Academy of Sciences, being himself a Member of that learned body.

Savery's patent for a steam or fire engine. (151.) In 1698, letters patent were granted to Captain Thomas Savery, (after his having erected, according to Dr. Robison, several Machines of this kind,) for securing to him the right of this invention.

In 1699, Savery exhibited a model of his engine before the Royal Society, and the experiments he made with it succeeded to the satisfaction of the Fellows. (See *Ab. Phil. Trans.* vol. iv. p. 398.) The figure, as represented in the *Philosophical Transactions*, is very obscure; but a more intelligible account is given in this author's Work, called the *Miner's Friend*, first published in 1699, and again in 1702. A neat diagram, and a very plain description of Savery's engine, is also given in Dr. Robison's *History of the Steam Engine*; see vol. ii. of his works by Brewster, from which the following is extracted.

Description of the engine. Pl. ix. Fig. 7. A (pl. ix. fig. 7) represents a strong copper boiler properly built up in a furnace. There proceeds from the top a large steam pipe B, which enters into the top of another strong vessel R, called the receiver. This pipe has a cock at C, called the steam cock. In the bottom of the receiver is a pipe F, which communicates side-wise with the rising pipe K G H. The lower end H of the pipe is immersed in the water of the pit or well, and its upper part K opens into the cistern into which the water is to be delivered. Immediately below the pipe of communication F there is a valve G, opening when pressed from below, and shutting when pressed downwards. A similar valve is placed at I, immediately above the pipe of communication. Lastly, there is a pipe E D, which branches off from the rising pipe, and enters into the top of the receiver. This pipe has a cock D, called the injection cock. The mouth of the pipe E D has a nozzle pierced with small holes, pointing from a centre in every direction. The keys of the two cocks C and D are united, and the handle g h is called the regulator.

Let the regulator be so placed that the steam cock C is open, and the injection cock D shut; put water into the boiler A, and make it boil strongly. The steam coming from it will enter the receiver, and gradually warm it, much steam being condensed in producing this effect. When it has been warmed so as to condense no more, the steam proceeds into the rising pipe, the valve G remains shut by its weight, the steam lifts the valve I, and gets into the rising pipe, and gradually warms it. When the workman feels this to be the case, or hears the rattling of the valve I, he immediately turns the steam cock so as to shut it; the injection cock still remains shut, (at least we may suppose this for the present.) The apparatus must now cool, and the steam in the receiver collapse into water. There is nothing now to balance the pressure of the atmosphere; the valve I remains shut by its weight, but the air incumbent on the water in the pit presses up this water through the suction pipe H G, and causes it to lift the valve G, and flow into the receiver R, and fill it to the top, if not more than twenty or twenty-five feet above the surface of the pit water.

The steam cock is now opened. The steam which, during the cooling of the receiver, has been accumulating in the boiler, and acquiring a great elasticity by the action of the fire, now rushes in with great violence, and pressing on the surface of the water in the receiver, causes it to shut the valve G, and open the valve I by its

weight alone, and it now flows into the rising pipe, and would stand on a level if the elasticity of the steam were no more than what would balance the atmospherical pressure. But it is much more than this, and therefore it presses the water out of the receiver into the rising pipe, and will cause it to come out at K, if the elasticity of the steam be sufficiently great. In order to ensure this, the boiler has another pipe in its top, covered with a safety valve V, which was Papin's invention, and which is kept down by a weight W, suspended on a steel-yard L M. This weight is so adjusted that its pressure on the safety valve is somewhat greater than the pressure of a column of water as high as the point of discharge K. The fire is so regulated, that the steam is always issuing a little by the loaded valve V. The workman keeps the steam valve open till he hears the valve I rattle. This tells him that the water is all forced out of the receiver, and that the steam is now following it. He immediately turns the regulator which shuts the steam cock, and now, for the first time, opens the injection cock. The cold water trickles at first through the holes of the nozzle f, and falling down into the steam, begins to condense it; and then its elasticity being less than the pressure of the water in the pipe K E D f, the cold water spouts in all directions through the nozzle, and quick as thought produces a complete condensation. The valve G now opens again by the pressure of the atmosphere on the water of the pit, and the receiver is soon filled with cold water. The injection cock is now shut, and the steam cock opened, and the whole operation is repeated; and so on continually.

(152.) After the step thus made by Savery, Papin published, in 1707, a small Treatise on the Steam Engine, in which he candidly acknowledges that Savery's scheme was not borrowed from any thing done in Germany. And it does not appear by this Work that he had at all prosecuted his original idea since 1698, at least not with any useful results. In 1705 he saw the engraving of Savery's engine, and in 1707 proposed his new construction, which, to do justice to his claims, it will be proper to describe, as he gives it, after knowing what Savery had effected.

It consisted of a boiler B, (fig. 8,) provided with a safety valve V; and a cylinder G H, connected to the boiler by a steam pipe S. The cylinder was closed at the top, and contained a floating piston P; and the base of the cylinder terminated in a curved tube T, which ascended into a cylinder M. The bent tube had a pipe Y from a reservoir of water communicating with it, and it was provided with a valve at r. Now suppose the cylinder G H to be filled with cold water by the pipe Y from the reservoir, and the boiler to contain strong steam; by opening the cock E, the steam would be admitted, and, pressing on the floating piston P, cause the water to ascend into the cylinder M; its return is prevented by the valve K, and the steam cock E being shut and the cock R opened, to let the condensed steam escape at the pipe R, the water from the reservoir refills the steam cylinder through the pipe Y, which is thus ready for repeating the operation. The water raised is to be directed to any useful object by the pipe D.

(153.) It is much to be regretted, that the question of the invention of the steam engine has led to a national controversy between the French and English: the one maintaining the claim of Papin, and the other that of the Marquis of Worcester. We believe we are quite free from any prejudice on this head, and will endeavour

Claims to the invention of the steam engine examined.

Manufac-
tures.

before entering upon a description of the further improvements, to pass in review the claims of the different authors to this time.

The Marquis of Worcester did certainly previous to 1663, the year of his death, throw out suggestions relative to the construction of some engine for raising water by the force of steam; and, according to his assertion, had actually constructed one, but his account is so mystified, that no one could benefit from it; and his only merit seems therefore to be, his having called the attention of others to the subject.

Sir Samuel Morland undoubtedly executed an engine of this kind in 1682, but unfortunately all traces of its actual form are unknown; and it seems to have excited but little attention, although from the statement he makes, of the space a quantity of water will occupy in the form of steam, which differs but little from the truth, it is evident that he had pursued the subject far beyond the Marquis of Worcester, to whom, however, he was in all probability indebted for his idea of the engine.

The next claimant is Dr. Papin, in 1698; but following the other two by some years, it seems absurd to give him the honour of the invention, as it is also to deny that he made some useful additions. The adoption of the safety valve and the floating piston were undoubtedly introduced by this author.

Papin and Savery were exercising their ingenuity so nearly at the same time, that nothing can be said as to priority; their merits can only be judged of by the results of their labours, and in this respect Savery has the greater claim. Probably at that time, as more recently, England furnished better opportunities for the exercise of the profession of the engineer than France or Germany, and every new engine erected most likely pointed out some new improvement, which gave to Captain Savery an advantage of which he availed himself; and since that time, England may almost consider the steam engine as a national Machine; to which she is largely indebted for her power and distinction amongst nations.

(154.) At present we have spoken only of Captain Savery's engine, as improved by himself; but as is said above, every new trial discovered defects, and suggested new improvements, not only to himself, but to others. The expense also attending the raising of water from the mines at that time, and the prospect which these several attempts offered, of benefiting the proprietors of those works, were powerful motives to the prosecution of further researches; and to this stimulus we are indebted for a very important change in the character of the engine by Newcomen, a smith, or ironmonger, at Dartmouth, who in conjunction with John Cawley, of the same place, and Captain Savery himself, obtained letters patent for the invention in 1705. The novelty in this construction consists in condensing the steam below an air-tight piston in a cylindrical vessel, having an open top; and the idea was very probably taken from the project of Papin's floating piston, but the mode of effecting the object was entirely different.

This engine is represented in (pl. x. fig. 1,) in which the injection water is seen issuing out of the pipe into the cylinder in the form of a jet. This important step is said by Desaguliers to have been the result of accident. According to this author, the condensation was originally made by the application of cold water on the outside of the cylinder, as first practised by Savery, while the piston was kept steam tight by water above floating on its

surface; and that while thus working an accidental hole in the piston having admitted a small quantity of water to fall into the cylinder, it caused a rapid condensation, and an equally rapid motion to the engine, a circumstance of which they were not slow to avail themselves, by giving to the injection cock the situation shown in the figure. This engine has received many improvements since this time; we are not, however, intending to describe the more modern atmospheric engine, but simply the improvements as far as they were carried by Newcomen himself. Here B represents the boiler, with its furnace for producing steam, and at a small height above the boiler is a steam cylinder C, of metal, bored to a regular diameter, and closed at the bottom, the top remaining open. A communication is formed between the boiler and the bottom of the cylinder, by means of a short steam pipe S. The lower aperture of this pipe is shown shut by the plate *p*, which is ground flat, so as to apply very accurately to the whole circumference of the orifice. This plate is called the regulator or steam cock, which turns horizontally on an axis *a*, which passes through the top of the boiler, and is fitted steam tight, and has a handle *b*, by which it is opened and shut. A piston P is fitted to the cylinder and rendered air tight by a packing round its edge of soft rope, well filled with tallow to reduce the friction, and its upper surface is kept covered with water to render it air tight. The piston is connected with the rod P A, which is suspended from the upper extremity D of the arched head of the lever by the chain A, this lever, or working beam, turning on the gudgeon G. The beam has also a similar arched head E F, at its other extremity, for the pump rod H, which receives the water from the mine. The end of the beam to which the pump rod is attached, is made to exceed the weight and friction of the piston in the steam cylinder; and when the water is drawn from such a depth, that the pump piston is too heavy for this purpose, counterpoise weights must be added at I, till the piston will rise in the steam cylinder at the proper speed. At some height above the top of the cylinder is a cistern L, called the injection cistern, supplied with water from the forcing pump R. From this descends the injection pipe M, which enters the cylinder through its bottom, and terminates in one or more small holes at N. This pipe has a cock called the injection cock, fitted with a handle. At the opposite side of the cylinder, a little above its bottom, there is a lateral pipe, turning upwards at the extremity, and provided with a valve at V, called the snifting valve, which has a little dish round it to hold water for keeping it air tight.

There proceeds also from the bottom of the cylinder a pipe Q, of which the lower end is turned upwards, and is covered with a valve *v*; this part is immersed in a cistern of water called the hot well, and the pipe itself is called the eduction pipe. To regulate the strength of the steam in the boiler, it is furnished with a safety valve, constructed and used in the same manner as that of Savery's engine, but not loaded with more than one or two pounds on the square inch.

The mode of operation remains to be described. Let the piston be pulled down to the bottom of the steam cylinder, and shut the regulator or steam valve *p*, then the piston will be kept at the bottom by the pressure of the atmosphere. Apply the fire to the boiler till the steam escapes from the safety valve, and then on opening the steam regulator, the piston will rise by the joint effect of the strength of the steam and action of the

Machinery.

Newco-
men's ori-
ginal en-
gine.
Pl. x.
Fig. 1.

Manufac-
tures.

excess of weight on the other end of the beam. When it arrives at the top of the cylinder, close the regulator *p*, and by turning the injection cock *O*, admit a jet of cold water, which condenses the steam in the cylinder, forming a partial vacuum, and the piston descends by the pressure of the atmosphere raising water by the pump *H* from the mine. The air which the steam and the injecting water contains is impelled out of the snifting valve *V*, by the force of descent, and the injection water flows out at the eduction pipe *Q*, and by repetitions of the operations, of alternately admitting steam and injecting water, the work of raising water is effected.

According to Desaguliers, *Exp. Phil.* vol. ii. p. 533. the operation of opening and shutting the cocks was done by hand till a boy named Humphrey Potter, who was employed for this purpose, in order that he might indulge in play, contrived, by means of cords and lines attached to the working parts of the Machinery and to the cocks, to make the engine perform this operation itself; the first step yet made towards rendering the Machine self-regulating, a principle which has been since carried perhaps to its utmost possible limits.

We have now traced the steam engine from its earliest date to the year 1712, at which time it had arrived at the state above described; and it must have been a great source of satisfaction to Savery to have himself witnessed and superintended the engine from its first effective working form, till it had attained this degree of perfection, although he was doubtless entirely indebted to Newcomen for the latter improvements. The great principle of the steam engine was now established, and only perfection of workmanship, and a better knowledge of the nature of steam, were requisite to render it competent to the discharge of very important duties.

We have, therefore, no longer to inquire into the history of the invention, but simply to illustrate the several improvements which have since been introduced into its construction; although the very great change the engine underwent in the hands of Mr. Watt seems to furnish a distinct epoch in its history. We shall accordingly treat the subject in this way, by first pointing out the improvements and suggestions which were made between this date, 1712, and 1769, when the latter philosophical inquirer undertook his earliest experiments on the subject.

In 1717 Henry Beighton, F. R. S. made several improvements in the connecting parts of Newcomen's engine, and was the first who attempted to reduce the power of the engine to computation.

Improve-
ments by
Beighton.

High pres-
sure engine
by Leupold.

Fig. 2.

(155.) In 1720 Leupold, the learned author of a Work on various mechanical subjects, proposed an entire new construction, which is now called the high pressure principle, the engine being worked by the pressure of steam acting against the atmosphere. This principle may be thus described. Over the boiler *B* (fig. 2) is placed two cylinders *CC*, fitted with steam-tight pistons *pp*. A four way steam cock *S* is placed between the boiler and cylinders, so as alternately to admit steam into one cylinder, and let it out from the other. The piston, by the admission of strong steam from the boiler below it, is raised, and depresses the other end of a lever connected to the rod of a plunger of a pump, which causes the water to rise through the pipe, and by the alternate action of the steam in the two cylinders, a continual stream of water is raised. Thus the first rude notice of the principle of employing high pressure steam upon a piston was given.

The four way cock employed in this engine, and since

so much in use, is also extremely neat, and was, in all probability, the invention of this ingenious writer.

(156.) The next writer of particular note on the subject of steam engines is Jonathan Hulls, who, so early as 1736, obtained a patent for applying the power of steam for the purpose of propelling vessels; an application of its power which has since worked such wonders in navigation. The title of the Pamphlet in which Hulls's invention or proposition is contained is, *A Description and Draught of a New Invented Machine for carrying Vessels or Ships out of or into any Harbour, Port, or River against Wind or Tide, or in a Calm*. The extraordinary progress of steam navigation within the last twenty years, and its still increasing importance, have led to different claimants for the honour of so important an invention; and this has brought to notice this old Pamphlet, which was very scarce, and probably the few copies saved, which establish the claims of Hulls, were preserved rather by accident than by any particular value set upon them by their possessors. The method is certainly complicated, and perhaps scarcely practicable; yet as the first idea of such an application of the power of steam, it is as a historical fact extremely curious and interesting. It appears to have altogether failed at that time, either for want of encouragement, or from the inefficiency of the apparatus.

Machinery.

Hulls's pa-
tent for
steam boats

(157.) It has been stated that a boy, Humphrey Potter, had contrived a means of making the engine open and shut its own cocks, and that this idea was rendered more permanent by Beighton. Other methods were, however, afterwards proposed by Gensanne, a Frenchman, and afterwards by De Moura, a Portuguese, who sent a model of his method to the Royal Society, which is described by Smeaton in the *Phil. Trans.* for 1751. See also Abridgement of the same, vol. x. p. 252. Subsequent improvements have superseded this contrivance, the general description of which will therefore suffice for this place.

Gensanne's
engine.

"The engine," Mr. Smeaton observes, "consists of a receiver, a steam and an injection cock, a suction and a forcing pipe, each furnished with a valve, with a boiler, which, on account of its bulk and weight, is not sent with the rest; but as it may be of the common globular shape, and having nothing particular in its construction, a description of it will not be necessary, as also the rest of those parts already mentioned which being essential to every Machine of this kind, a further account of them may be dispensed with. What is peculiar to this engine, is a float within the receiver, composed of a light ball of copper, which is not loose in it, but fastened to the end of an arm, made to rise and fall by the float, while the other end of the arm is fastened to an axis, and, consequently, as the float moves up and down, the axis is turned round one way or the other. This axis is made conical, and passes through a conical socket, which last is soldered to the side of the receiver. On one of the ends of the axis, which projects beyond the socket, is fitted a second arm, which is also moved backward and forward by the axis, as the float rises or falls. By these means, the rising or falling of the surface of the water within the receiver communicates a correspondent motion to the outside, in order to give proper motions to the rest of the gear, which regulates the opening and shutting of the steam and injection cocks, and serves the same purpose as the plug-frame, &c. in Newcomen's engine."

tures.

First scien-
tific inquiry
into the
power of
steam by
Payne.

ments had taken place in the working parts of the atmospheric engine of Newcomen, yet nothing like scientific principles had been employed to ascertain the actual force of the powerful agent by which it was put into motion; but in this year Mr. J. Payne undertook an investigation of this kind, and published an account of his experiments in the *Phil. Trans.* for 1741. See Abridgement, vol. viii. p. 518. Unfortunately, he did not employ a thermometer, and, therefore, his results are not so accurate as they might otherwise have been: they, however, led the way to further researches, and were very ingenious. He procured a copper globe of twelve inches diameter, having two cocks fitted to it and a small valve. The vessel thus prepared was hung over a large vessel, in which water was rarefied into steam, and by a pipe the steam was admitted at one of the cocks into the globe, and the other being also open, the steam being allowed to blow through, forced out the air that was in the globe, and supplied its place, when both cocks were suddenly shut, and the globe taken down and hung over a vessel of cold water with the lower cock immersed in water. The cock was opened under water, on which the water rushed violently into the globe till it had supplied the vacuum, when the cock was again shut, and the globe, with the water, was put in the scales and found to weigh 713 oz. which, taken from 727 oz., the whole weight before, there remains only 14 oz., the difference, from which he inferred that all the air was nearly excluded out of the globe by the steam. He again excluded the air out of the globe with steam as before, and both the cocks being closed, with the globe full of steam, he put the globe in the scales and it weighed 202.5 oz. He then opened one of the cocks and let in the air, and by adding weight in the other scale it was found to weigh 203 oz., which showed that the weight of the air the globe contained was 5 oz., or 218.75 grains. The globe being filled with steam as before, and condensed with cold water on the outside of the globe, and the metal again made very dry, and the air let into the globe, the water from the condensed steam was found to weigh 96 grains. It is worthy of remark here, that this gives the density of steam at 212° , or that of air at 60° , as 96 : 218.75, or as 0.44 : 1. The true density of steam at 212° , is nearly as 0.48 : 1.

The globe was now filled with steam as before, but not knowing the effect of temperature, he continued the globe longer with the steam passing through it, by which it acquired a greater degree of heat; for he had found by these experiments, that the least degree of cold less than the steam, would condense a part of it again into water, and hence the quantity could not be ascertained which would exclude the air out of a given space, which was the chief end of the experiment. In this experiment he succeeded in excluding the air with less steam; for, on weighing the globe, when the steam was condensed, the air let in, and all cold, it was found the weight of the water condensed from the steam was only about forty-eight grains, which filled, when converted into steam, 925 cubic inches of space, so as to exclude nearly all the air. From which he concluded that one cubic inch of water will form 4000 inches of steam. To admit of comparison the temperature should have been observed, as there is little doubt that the steam was so rarefied by heat as to cause this result.

Mr. Payne also attempted to introduce a new mode of generating steam: this apparatus consisted of a cast-iron vessel of the figure of the frustrum of a cone, its

diameter at the bottom being four feet, with a semi-globular end of copper about five feet and a half diameter. In the inside a small vessel was inserted, which Payne called a *dispenser*, which vessel had pipes round the sides fixed to it; the bottom rested on a central pin, on which it revolved, so as to spread the water it received from above through an iron pipe. The end of this pipe passed up through the head, and was enclosed very tightly, but so as to be easily moved with a circular motion, whereby the water might be dispersed or showered round on the sides of the red-hot cone, or ignited vessel, in a very exact manner. From experiment he states,

1. That a pot or vessel, of the size and shape here mentioned, will, being kept to a dark red heat and the water regularly dispersed, rarefy or expand fifty gallons of water, wine measure, per hour.

2. That a cubic inch of water will make in practice 4000 inches of steam; or that the elastic steam of one cubic inch of water is sufficient to exclude the air out of a vessel which is in content 4000 inches. This, as said above, must have been at a high temperature.

3. That the above fifty gallons will produce 46,000,000 cubic inches of elastic steam per hour, which is per minute 770,000.

4. That the second pot or vessel (there being two in his Machine) will rarefy or expand forty gallons of water, wine measure, per hour, and will produce 36,960,000 cubic inches of elastic steam per hour, which is per minute 616,000 inches.

5. That both being united together, make 1,386,000 cubic inches of steam every minute, for 346 inches of water.

6. That by an experiment made by a fire-engine, forty gallons of water per hour, made into elastic steam in this method, will effectually give motion to a twenty-four-inch cylinder fire-engine.

7. That by true experiments made at Wedgbury and Newcastle on Tyne, 112 pounds of pit coal will and are sufficient in this method to expand or rarefy ninety gallons of water per hour into an elastic steam or vapour.

8. That by the best accounts and observations he could get and make, they consume under their boilers, to make the same quantity of steam, three hundred weight of pit coal in working a fire-engine one hour.

9. That ninety-five gallons of water per hour, expanded or rarefied into steam, will work a thirty-six-inch cylinder engine.

From these observations Mr. Payne concluded that this invention would save at least sixty per cent. in pit-coal to work a fire-engine, according to the work at that time effected by the usual operation.

These results are near the truth of what may be done, but the method has no advantages, and the apparatus soon fails. It is a duty, however, to an ingenious man to record his attempts to establish useful truths even when he fails in his object. It shows the state of knowledge at the time on these subjects, and it saves others from repeating useless experiments. The mode of generating steam we have just described has been more than once revived lately.

(159.) This scientific examination, however defective, of the power of steam and of the means of generation, was soon followed by other researches, and first by Mr. Francis Blake, F.R.S., who, in 1751, undertook an investigation relative to the best proportions for steam engine cylinders of given content, which was published in the *Phil. Trans.* for that year. See also Abridgement of *Phil. Trans.* vol. x. "It is evident," the author observes,

New mode
of generat-
ing steam
by the
same.

Machinery.

Manufac-
tures.

" in the first place, from a general law of Mechanics, that the content of the cylinder remaining the same, the quantity of water discharged at each lift will in all cases be equal, by only adjusting the distance of the centre of the piston from the fulcrum of the balance. It will be granted also that the excess of the column of atmosphere above that of the water, is a weight on the piston, driving it to a depth of about five feet, by the present construction, within the cylinder, acceleratedly, till friction and an impediment from the steam, which remains in the cylinder, even after the jet d'eau, and is increased in elasticity while its bounds are diminished, shall equal the accelerative force; and that then again the piston is retarded the rest of the way. It may be convenient to remark too, that if the rarefaction be so complete that the descent would be greater than the construction admits of, the retardation is augmented by an arm of the balance pressing on springs. But to say nothing of friction here, we can, notwithstanding this diminution of force by the remainder of steam within the cavity of the cylinder, demonstrate the ratio of the velocities, and the times of descent of the pistons, in cylinders of unequal altitudes, to be exactly the same as if the resistance was nothing; whence we shall without difficulty arrive at the same conclusion in this matter.

M N, in the annexed diagram, is the working part of a steam engine cylinder, of the usual height, equal in diameter to a shorter one m n; and the rarefaction in both of them being supposed the same, A Q = a q, R Q = r q, and A R = a r, may represent the excess of the atmosphere's weight above the column of water, the resistance to the pistons from the remainder of the steam, and the effective force respectively, e g, at the beginning of the descent.

Take then every where $a k : A K :: a n : A N$, and at all similar positions the resistance $b c$ of $m n$, and force $k c$ on its piston, will be equal to the resistance $B C$ of $M N$, and force $K C$ on its piston, and by well known principles we have $\sqrt{a k c r} : \sqrt{A K C R} ::$ celerity in k : celerity in K . But these areas being evidently as the corresponding parallelograms $k q$ and $K Q$, and these again as their heights, the celerities generated are in the subduplicate ratio of $a k : A K$, as if the resistance had been nothing; and by an obvious reasoning from the said proposition, the times also appear to be in the above-mentioned ratio, which ratio is not in any way varied, though the resistance prevails from the intersecting points o .

Now, to apply what has been said to the business in

hand: if T W be a cylinder of equal content with the cylinder M N, the quantity of water delivered by both will, as a consequence of the fundamental law of Mechanics observed above, be the

same at each lift. But the cylinder T W is no higher than $n m$, and therefore their

rarefactions are equal; hence by what has been proved with regard to the times, the time of the piston's descent in T W will be to that of the piston's descent in M N : $\sqrt{E W} : \sqrt{A N}$; whence in any given time the broad cylinder T W will perform more than the longer one M N of equal content, and that in the ratio of their diameters; for $F E^2 \times E W = M A^2 \times A N$, and $E W : A N :: M A^2 : E T^2$, consequently $\sqrt{E W} : \sqrt{A N} :: M A : T E$. The friction too is diminished with the slowness of the motion, because the periphery increases in a less ratio than does the area of a circle.

The result of the whole then is in favour of the broad cylinder; and still the broader the better; for unless some mechanical considerations should limit the problem, it is evident, in a geometrical sense, that there is no limitation. A disadvantage might arise perhaps to the effect of the jet d'eau from thus increasing the breadth; which, however, would probably be remedied by a number of these jets: but be that as it may, it is certain that to augment the diameters, and diminish the lengths of the smaller kind of cylinders now used, could have no such inconvenience, nor fail of being attended with an augmentation of force.

(160.) The next writer and practical operator in the improvement of the atmospheric engine, and who forms as it were the link which connects the first with the second epoch of the history of the steam engine, was the celebrated Smeaton, who erected several atmospheric engines, and brought them to a degree of perfection which has scarcely been exceeded in later times, principally, however, by a more judicious proportioning of the several parts to each other than had been before practised. and not by any alteration in the nature of its action. Having been called upon to erect several large engines of this kind, he found at first that he had to struggle with many difficulties, and they did not in all cases answer his expectation, sometimes requiring much more fuel than he had reckoned upon, and at others falling short of their anticipated duty; circumstances which led him to undertake the construction of an experimental engine, and which was also the first portable steam engine.

In this engine the fire-place was formed wholly within the boiler, and the arch ends of the beam he employed were segments of a wheel of 6.2 feet in diameter, with a chain communicating the motion from the piston to the pump rod; the diameter of the cylinder was 18 inches, its area in circular inches having been of course 324 inches; and allowing 7 pounds to the circular inch, which such a cylinder, he remarks, would very well carry, we have 2268 pounds for the whole pressure upon it. The length of its stroke was 6 feet, of which strokes it made 10 per minute, so that its duty was $2268 \times 6 \times 10 = 136,080$ pounds raised a foot high per minute, which he called a six-horse engine, reckoning the horse power 22,680 pounds, nearly as we stated it in Art. 2. It was not, however much more than a four-horse power according to the usual estimate. With this engine Mr. Smeaton made a number of experiments greatly diversified in their character, and thereby calculated to furnish every requisite information relative to this description of engine. From these experiments he deduced a variety of important proportions and results, the particulars of which are given in the following Table; and these proportions he afterwards followed in the construction of several first-rate engines, some of them exceeding one hundred horses' power.

It may be proper to explain in what way the column in the above Table marked Great Product per Minute was obtained. This was by multiplying together the space described by the loaded piston per minute in feet, its area in circular inches, and again by the pressure per circular inch, estimated in feet of a column of water equal to that pressure. Thus a 26-inch cylinder, whose pressure per circular inch is equal to 18 feet of a column of water of an inch circular base, and whose speed is 76.21 feet per minute, gives for its great product

$$26^2 \times 18 \times 7.62 = 927,323.$$

All the other columns of the Table are sufficiently obvious by the description at their heads.

The experiments above recorded were made about the year 1765, but it was not till 1774 that Smeaton made the first effective improvement from them on an engine at large, when it appeared that he had reduced the expenditure of fuel about one-third. In 1775 he designed the Chase water engine, the cylinder of which was 72 inches in diameter, and the stroke 9 feet. Its power was equivalent to the exertion of 108 horses, and its consumption of fuel was estimated at 1136 pounds of Newcastle coal per hour. At its full power it was proposed to make nine strokes per minute, but to be regulated by the cataraet to four strokes and a half per minute. The construction of the beam and other parts of the engine are sufficiently curious to entitle it to the strict attention of the student of the subject. See Smeaton's *Reports*, vol. ii.

There seemed to be few practical circumstances that escaped Smeaton's inquiry respecting the atmospheric engine; and he drew up for his own use the Table of Proportions, &c. as given above. The Table was not published by the author, but is found in the collection of his papers, purchased by the late Sir Joseph Banks, and now in the possession of the Royal Society. It was first printed in Rees's *Cyclopædia*. But the most important of his researches relate to the load upon the piston; on which he remarks, he had found engines calculated to carry a load varying from under five pounds to upwards of ten pounds to the square inch: those lightly loaded being expected to go with the greatest velocity, so that an engine carrying five pounds to the inch must go with double the velocity of one loaded to ten pounds, the cylinders being of equal area, in order that the effects of the power might be equal. He further adds, in engines, however, as in other Machines, there is a maximum which, without new principles of power, cannot be exceeded. Bad proportions of the parts and bad workmanship may make an engine fall short, in any degree, of what it should do, but its maximum cannot be exceeded by the most accomplished artists. The best speed is now considered to be 220 feet per minute.

(161.) Experiments had, however, in some degree, been directed to a mean burden. The original patentees, (Newcomen and Co.) from some of their first performances, laid it down as a rule to load the piston, so as but little to exceed eight pounds to the inch; but, on more expe-

rience they diminished that load, and amongst the best engines previous to Smeaton's own time, the load was made about seven pounds to the square inch. And he further states, that any proportions will do if the parts be properly proportioned; but, from a long course of very laborious experiments, he had fixed his scale near upon, but somewhat under eight pounds to the inch, including raising the injection water; and this agrees with the load in the best duty engines at this day in Cornwall.

The labours of Smeaton show the imperfect state of Mechanical Science as applied to practice in a remarkable degree, for he designed an engine to be erected at Long Benton to raise water for turning a water wheel to draw coals from a pit; and in 1781 proposed one of Boulton's and Watt's engines to be erected for raising water for driving a corn-mill at Deptford; using such arguments as the following in support of his opinion. "It is to be apprehended," he says, "that no motion communicated from the reciprocating beam of an engine, can ever act with perfect equality and steadiness in producing a circular motion, like the regular efflux of water in turning a water wheel; and much of the good effect of a water-mill is well known to depend upon the motion communicated to the millstones being perfectly equable and smooth; the least tremour or agitation takes off from the complete performance." Secondly, all the engines he had seen were liable to stoppages, and so suddenly, that in making a single stroke the Machine is capable of passing from nearly its full power and motion to rest; for whenever the steam gets lowered in its heat below a certain degree, for want of renewing the fire in due time or otherwise, the engine is then incapable of performing its functions. In the raising of water (a business for which the fire engine seems peculiarly adapted) the stoppage of the engine is of no other ill consequence than the loss of so much time, but in the motion of millstones grinding corn, such stoppages would have a particularly bad effect.

We have now traced the history of the invention of the steam engine from its first rude unscientific form, to that period when it was to undergo a most important change in the hands of Watt, but our last descriptive delineation of it is as it existed in 1712, between which period and that we have now arrived at, 1769, many of the improvements already mentioned, and great accuracy of workmanship, had altogether changed the form and mechanism of it, although without any change in its principle of action. Before, therefore, closing this epoch in the history of this important Machine, it would have been proper to exhibit to the reader the nature and form of the atmospheric or Newcomen's engine, after the practice and experience of more than fifty years; but as the engine in this state is given in our theoretical Treatise on MECHANICS, it will be, perhaps, sufficient to refer the reader to that volume; and we shall simply remark here that the great merit of Newcomen was that he separated, as we have already explained, those parts of the engine in which steam was to act, from those in which the water was to be raised, employing a beam between them, the steam being used merely for displacing the air, and then forming a vacuum by condensation.

(162.) It may be proper to observe, that although we have said but little relative to the original engine of Savery, after having described his latest improvement in it, in 1712, yet it was not left in that state; several persons, notwithstanding the improvements of Newcomen, still preferred the former engine, and even since Watt's

patent, attempts have been made to employ in some cases the principles of Savery: a few lines will not, therefore, be misapplied to point out the peculiarities of these inventions, their authors, dates, &c.

The first we need mention of this class was Blakey, who in 1776 took out a patent for certain improvements in Savery's engine; one of which consisted in employing floating oil upon the surface of the water in the receiver, to form a piston or disc between the steam and cold water: or air was to be admitted into the receiver for the same purpose.

In this case two receivers were to be used, one in the same situation as Savery's, which was to receive the air; and the hot steam, when admitted into it, forced the air to descend by a pipe to a second receiver, which was at the bottom of the well, and expel the water therefrom, and elevate it in the force pipe. By this means he hoped to prevent the steam coming in contact with the water, and thus to avoid the condensation.

Mr. Blakey afterwards made some alterations in the form of his engine, which is described as follows by Mr. Ferguson. (See pl. x. fig. 3.) E is the boiler, set in a furnace so as to be surrounded with flame. F is the gauge cock, to ascertain the depth of the water in the boiler. D the steam pipe, to which is soldered the cock and funnel C, for filling the boiler before the engine is set to work. I is an air vessel, and T T an injection pipe, which passes through across the top of the receiver, and has small holes pierced in it for the cold water to drop through, and fall in a shower in the air vessel I, in order to form a condensation; the end of the injection pipe is carried into the steam pipe D to admit a small quantity of water to run down the pipe D, and supply the boiler. V is a receiver, communicating with the air vessel I by a pipe; in the upper part of it is a colander S, with small holes to disperse the injection water, which falls from the air vessel I equally through the receiver V. O is a valve to admit air, which comes through the cock P into the receiver; and H is an occasional cock, to let out the air and steam when the engine is first set to work. Q is a pipe from the receiver V to the box which contains the valves B and N at the bottom of the forcing pipe A, which conveys the water up to the receiver. M is the suction pipe, to draw the water from the well up to the receiver. G is the fire-place belonging to the furnace, in which the boiler is set, and beneath it is an ash-hole. It is needless to say any thing of the scaffold or well, they being always made in proportion to the size of the Machine, and according to the place in which it is to be erected. All the vessels and pipes of this engine are made of strong copper.

In order to set this engine at work, the receiver and pipe A A must be filled with water, which will be retained by the clack B; then more water must be poured into the funnel C, which is on the steam pipe D; from thence it falls into the boiler E, and rises to the level of the cock F, which must be open; but as soon as the water runs from it, the funnel cock C, as well as the gauge cock F, must be shut, and the air gauge cock H must be opened. The fire is then to be put into the furnace G, and as soon as the water is in ebullition in the boiler it creates steam, which finds its way through the pipe D, and forces the air out of the vessel I into the lower receiver V: the air is also forced out at the cock H, the steam following it with great velocity. In a second or two the cock H must be shut, and instantaneously the injection cock L must be opened, which lets

Manufac-
tures.

cold water run through the end of the pipe T T into the steam pipe D, to replace that which has been evaporated out of the boiler E; and it also rushes out on all sides from the little holes which are in the sides of the pipe T T into the air vessel I, and falls on the colander S. This cold water makes a sudden condensation in the vessels I and V, and forms a vacuum, which causes the atmosphere to press on the water, in which the lower end of the pipe N is immersed, and the water ascends the said pipe with great rapidity, and passes through the clack N, and through the pipe Q into the receiver V, till it rises up to O, where is a floating ball fastened to a handle or lever, which in rising turns the key of the cock P, and opens it. There is a valve at the end of the cock which is inside the receiver V, so that as soon as the cock is opened, the valve O is forced up by the air, which rushes through with great quickness and noise into the vessel I; and when that vessel is full of air, the vacuum is destroyed, and no more noise is heard, which gives the notice to shut immediately the injection cock L; that being done, the steam recovers its force, and makes its way through the steam pipe D into the air vessel I; and as the steam increases, being much lighter than the air, it keeps uppermost, and forces the air on the water which is in the receiver V, which water is forced through the pipe Q, and lifting up the clack at B, goes up the pipe A and empties itself into the receiver at top. When all the water is expelled out of the receiver V, the air follows and ascends with great velocity through the water which is in the pipe A. Two or three seconds after the noise of this is heard, the injection cock L must be opened to let in cold water, and cause the same effect as before. The noise of the air rushing in and out of the receiver, gives proper notice when the manager of this hand engine is to open and shut the injection cock, which is the only thing required to work this Machine, when once it has been put in action, in the manner that has been described before.

This engine was not found to answer any better than Savery's, because the air will not make that complete separation between the steam and the cold water which the inventor expected; and there is a great loss of power in compressing the air sufficiently to make it lift the column of water; and in order to get rid of this air, it must be forced up the pipe, which takes as much power of steam as would be required to force up as much water as the air occupied the place of when in its condensed state. Mr. Blakey's intention in the injection of a small quantity of water into the boiler at every stroke, was the same as Mr. Payne's red-hot boiler, of which we have before spoken; but he was in practice obliged to employ a steam cock in the pipe D, otherwise the steam which the boiler produced while the injection cock was open would have been all condensed and lost.

Savery's engine can be usefully employed for lifting water thirty or thirty-five feet, which can be done principally by suction, and with a very slight pressure for the remainder; but it is the most advantageous way to raise no more than twenty-four feet, and perform the whole lift by the suction, and even to allow the water a sufficient descent to empty the receiver by its own gravity, without forcing it in the least by the steam. In this form of the engine, the steam need have no greater elastic force than the atmospheric air, or just as much as is sufficient to make it enter into the receiver, as the water runs out. The temperature of the steam, according to our Table, will then be only a little above the boiling point,

or above 215° , and, consequently, the loss by the condensation is not so serious; and as the steam is not pressed upon the water, it is not brought into such close contact with the cold water, as in the forcing engines. In this way the injection must be forced in by a small force pump.

(163.) *Pontifax's improvement.*—The most modern application of Savery's principle was that made by Mr. Pontifax, for which he took out a patent in 1819: this is shown in pl. x. fig. 4, 5, in which, fig. 5 is a back elevation, and fig. 4 a side elevation of the engine: *b b*, fig. 5, are two steam cylinders connected by cross tubes at *c c*, in each of which a vacuum is alternately formed by the condensation of elastic vapour, conducted from the boiler by the bent tube *d*, and admitted to the steam cylinders by means of a sliding valve.

f f, fig. 5, are two tubes perforated with small holes for the admission of steam and injection water, the latter of which is distributed by falling on the stirrup *g*. At *h*, fig. 4, is seen the suction pipe proceeding to the bottom of the well, which in no case ought to exceed from twenty-eight to thirty feet in depth; so that a vacuum being formed in the copper vessels *b b*, the water will be raised by the pressure of the atmosphere, and passing up the tube *h*, will take the place of the elastic vapour. Two valves are placed at the upper end of the suction pipe *h*, which allow of the upper passage of the water from the well, but prevent its return; two similar valves open into the air vessel *k*, to which is attached the nozzle *l*, serving to convey the water from the copper vessels to any required point; *m* is the injection tube, furnished with a valve at *o*, and intended to convey water from the box *n* to the taper tubes *f f*. A stop cock is seen at *p*, to regulate the supply of condensing water; *q* is a tube passing from the bottom of the cistern *n* to the injection tube *m*, and furnished with a stop cock at *s*.

The quantity of water in the cistern *n* is regulated by a floating valve *t*, which in fig. 5 is represented immediately over the pipe *q*, so that the valve is opened whenever the water rises beyond the required depth. *u u* are two tubes communicating with the back part of the chambers *n n*, and the inverted vessels *v v*, each tube being furnished with a valve at *w*, to admit the water from the chamber to the buckets *x x*. The two buckets *x x*, which are suspended by rods, and a chain passing over the wheel 2, which is fixed on the end of the axis 3, and supported by a bracket 4. From the other end of the axis projects an arm 6, provided with a stud 7: 9 is a view of the horizontal axis turning in a stuffing box at 10, on one end of which is fixed a pinion, which serves to give motion to the sliding valve.

To put this engine in action, the steam must be first raised to the boiling point, and the valve or cock opened, which admits it to pass from the boiler to the pipe *d*. One of the buckets must now be made to descend, which will open the sliding valve *u*, and admit the steam into the cylinder *b*. The atmospheric air, which will thus be expelled from the cylinder, is allowed to pass through the valve *j* and nozzle *l*. The other bucket must then be depressed, and by its action upon the sliding valve it will open a communication for the injection water through the pipe *q q*, which, passing down the perforated tube *f*, will immediately condense the steam, and form a vacuum in the vessel. The whole pressure of the atmosphere being now removed from the suction pipe *h*, the water will rush up to restore the equilibrium, and the vessel *b* being filled will furnish a supply at the bent tube *l*.

Machinery.

Pl. x.
Fig. 4, 5

Manufac-
tures.

Having examined the action of one half of the apparatus, we may suppose the same effect to be produced on the opposite side. The steam will, in the first instance, be admitted by the pipe *c*, and a communication afterwards opened by means of the sliding valve with the condensing water, which by reducing the steam to its original bulk will form a vacuum, and the water will again ascend as in the first vessel.

The stop cock *y* must now be opened, and the bucket *x* first described made to ascend, which will remove the sliding valve *e* to its original position, and admit the steam to the upper part of the first vessel, which will depress the water, and cause it to flow through the valve *j* and nozzle *l*, while at the same time the water will pass through the tube *u u*, in which the valve *w* is inserted beneath the inverted vessel *v*. The water will continue to enter the bucket *x* till its increasing weight causes it to preponderate, and turn the sliding valve *e* in the opposite direction.

Should there not be a sufficient supply of water in the cistern *n n* for the purpose of condensing the steam in the large vessels, the stop cock *p* must be opened, and an additional supply of water will then be furnished from the chambers *n n* by the tube *m*; and in the event of the bucket not being depressed at the instant that the water is expelled from the chamber *n* of the vessel *b*, the steam will pass through the tube *u u*, and act between the under side of the fixed inverted vessel *v*, and the surface of the water in the movable bucket being accelerated by the repellent force of the steam, so that by the alternate action of the buckets *x x* the motion of the engine is rendered continuous.

It appears that each steam vessel in the engine employed at the City Gas Works contained about thirty-six gallons of water, which is raised about twenty-eight feet three times every two minutes; one bushel of coals, or two of coke, serving the boiler about two hours and three-quarters.

Brown's gas engine is also similar in its principle to Savery's engine, except that the operating agent is gas instead of steam. An engine of this kind is at work at Croydon, in Surrey, and is said to be performing satisfactorily. Several other attempts to improve this early engine have been made by Mr. Keir and others, but we believe it will not be necessary to interrupt the general train of the history of the steam engine by describing them. We now proceed, therefore, to treat of the great changes effected in it by Mr. Watt.

Mr. Watt's Improvements,

IId Period, from 1769 to 1800.

Mr. Watt's
improvements.

(164.) We now arrive at an entire new era in the history of the steam engine. It had not to this time even acquired that denomination, but was generally known as the fire engine; it now for the first time became effectually a steam engine, by the substitution of steam for propelling the piston instead of the atmospheric pressure. While the atmosphere was employed to produce the effective downstroke of the piston, and cold water floating on this piston to preserve it steam tight, it was impossible to preserve the cylinder at a tolerably high temperature; but this was still further rendered impracticable by the means used for producing the condensation. And these were two of the great questions to which Mr. Watt directed his attention, and for which he found the most ample remedies. Another important proposition is con-

tained in his first patent, namely, to work the steam expansively, that is, to cut off the admission of steam to the cylinder sometime before the stroke is completed, which has a very advantageous effect. See Art. 142, of the last Chapter.

The enumeration of these improvements will convey to the reader, not versed in the nature of the steam engine, a very inadequate idea of their importance; it is, however, to them we are in a great measure indebted for the extraordinary pitch to which Machinery and Manufactures have since been carried in this Country; they are therefore entitled to more than ordinary notice.

(165.) It appears that so early as 1761, Mr. Watt had made experiments with a Papin's digester on the power of steam, and that in the winter of 1764 he had his attention again directed to the subject, by being called upon to repair a small working model of a Newcomen's engine belonging to the University of Glasgow. At that time it appears, from his own statement, that what knowledge he possessed on the subject he derived only from Desaguliers and Belidor; and he set about the repairs as a mere mechanic; and when that was done and it was set to work, he was surprised to find that its boiler could not supply it with steam, though apparently quite large enough; (the cylinder of the model being two inches in diameter, with a six-inch stroke, and the boiler about nine inches diameter;) by blowing the fire it was made to make a few strokes, but required an enormous quantity of injection water, though it was very lightly loaded by the column of water on the pump. It soon occurred that this was caused by the little cylinder exposing a greater surface to condense the steam, than the cylinders of large engines did in proportion to their contents; it was found also that by shortening the column of water in the pump, the boiler could supply the cylinder with steam, and that the engine could work regularly with a moderate quantity of injection. It then appeared that the cylinder of the model being of brass, would conduct heat much better than the cast-iron cylinders of larger engines, (generally covered on the inside with a stony crust,) and that considerable advantage could be gained by making the cylinders of some substance that would receive and give out heat slowly. Of these wood seemed to be the most likely, provided it should prove sufficiently durable. A small engine was therefore constructed with a cylinder six inches diameter, and twelve inches stroke, made of wood, soaked in linseed oil, and baked to dryness. With this engine many experiments were made; but it was soon found that the wooden cylinder was not likely to prove durable, and that the steam condensed in filling it still exceeded the proportion of that required for large engines, according to the statements of Desaguliers. It was also found that all attempts to produce a better exhaustion by throwing in more injection water, caused a disproportionate waste of steam.

By experiments which he then tried upon the heats at which water boils under several different pressures greater than that of the atmosphere, it appeared that when the heats proceeded in an arithmetical, the elasticities proceeded in some geometrical ratio; and by laying down a curve from his data, he ascertained the particular one near enough for his purpose. It also appeared, that any approach to a vacuum could only be obtained by throwing in large quantities of injection, which cooled the cylinder so much as to require great quantities of steam to heat it again, out of proportion to the power gained by the more perfect vacuum; and that

His first ex-
periments

Experi-
ments con-
tinued.

Manufac-
tures.

the old engineers had acted wisely in contenting themselves with loading the engine with only six or seven pounds on each square inch of the area of the piston. It being evident that there was a great error in Desaguliers's calculations of Mr. Beighton's experiments on the bulk of steam, a Florence flask, capable of containing about a pound of water, had about one ounce of distilled water put into it, a glass tube was fitted into its mouth, and the joining made tight by lapping that part of the tube with packthread, covered with glazier's putty. When the flask was set upright, the tube reached down near to the surface of the water, and in that position the whole was placed in a tin reflecting oven before a fire, until the water was wholly evaporated, which happened in about an hour, and might have been sooner effected had he not wished the heat not much to exceed that of boiling water. As the air in the flask was heavier than the steam, the latter ascended to the top, and expelled the air through the tube. When all the water was evaporated, the oven and flask were removed from the fire, and a blast of cold air was directed against one side of the flask, to collect the condensed steam in one place. When all was cold, the tube was removed, the flask and its contents were weighed with care, and the flask being made hot, it was dried by blowing into it with bellows, and when weighed again was found to have lost rather more than four grains, estimated at four and a half grains. When the flask was filled with water, it was found to contain about $17\frac{1}{8}$ ounces avoirdupois of that fluid, which gave about 1800 for the expansion of water converted into steam of the heat of boiling water.

This experiment was repeated with nearly the same result; and in order to ascertain whether the flask had been wholly filled with steam, a similar quantity of water was for the third time evaporated; and, while the flask was still cold, it was placed inverted, with its mouth (contracted by the tube) immersed in a vessel of water, which it sucked in as it cooled, until in the temperature of the atmosphere it was filled to within half an ounce measure of water. In repeating this experiment afterwards, Mr. Watt simplified the apparatus by omitting the tube, and placing the flask on its side in the oven, partly closing its mouth by a cork, having a notch on one side, and in other respects proceeding in the manner above mentioned.

These experiments are not stated by Mr. Watt as extremely accurate, the only scale beam he had at the time at his command not being very sensible, and the bulk of the steam being liable to be influenced by the heat to which it was exposed, which in the way described was not easily regulated or ascertained; and from further experiments it appeared that the expansion was more than was thus computed. These experiments were as follows.

Another
series.

(166.) A boiler was constructed which showed, by inspection, the quantity of water evaporated in any given time, and whereby could be ascertained the quantity of steam used in every stroke by the engine, which was found to be several times the capacity of the cylinder. Mr. Watt, astonished at the quantity of water required for the injection, and the great heat it had acquired from the small quantity of water in the form of steam which had been used in filling the cylinder, and thinking he had made some mistake, tried the following experiment. A glass tube was bent at right angles, one end was inserted horizontally into the spout of a tea-kettle, and the other part was immersed perpendicularly in well water contained in a cylindric glass vessel, and steam

was made to pass through it until it ceased to be condensed, and the water in the glass vessel was become nearly boiling hot. The water in the glass vessel was then found to have gained an addition of about one-sixth part from the condensed steam. Consequently, water converted into steam can heat about six times its own weight of well water to 212° , or till it can condense no more steam. Being struck with this remarkable fact, and not understanding the reason of it, Mr. Watt mentioned it to his friend Dr. Black, who then explained to him his doctrine of latent heat, which he had taught for some time before this period. See Art. 125.

On reflecting further, it was perceived, that in order to make the best use of steam it was necessary, first, that the cylinder should be maintained always as hot as the steam which entered it; and, secondly, that when the steam was condensed, the water of which it was composed, and the injection itself, should be cooled down to 100° , or lower, where that was possible. The means of accomplishing these points did not immediately present themselves; but early in 1765 it occurred to Mr. Watt that if a communication were opened between a cylinder containing steam and another vessel which was exhausted of air and other fluids, the steam as an elastic fluid would immediately rush into the empty vessel, and continue so to do until it had established an equilibrium; and if that vessel were kept very cool by injection, or otherwise, more steam would continue to enter until the whole was condensed. But both the vessels being exhausted, or nearly so, how was the injection water, the air which would enter with it, and the condensed steam to be got out? This, says Mr. Watt, I proposed, in my own mind, to perform in two ways. First, by adapting to the second vessel a pipe reaching downwards more than 34 feet, by which the water would descend, (a column of that length overbalancing the atmosphere,) and by extracting the air by means of a pump.

The second method was by employing a pump, or pumps, to extract both the air and the water, which would be applicable in all places, and essential in those cases where there was no well or pit.

(167.) This latter method was the one preferred, and is the only one now ever thought of. In Newcomen's engine the piston is kept tight by water, which could not be applicable in this new method; because if any of it entered into a partially exhausted and hot cylinder, it would boil and prevent the production of a vacuum, and would also cool the cylinder by its evaporation during the descent of the piston; to remedy this defect Mr. Watt employed wax, tallow, or other grease, to lubricate and keep the piston tight. It next occurred to him that the mouth of the cylinder being open, the air which entered to act on the piston would cool the cylinder, and condense some steam on again filling it; he therefore proposed to put an air-tight cover upon the cylinder, with a hole and stuffing box for the piston rod to slide through, and to admit steam above the piston to act upon it instead of the atmosphere. There still remained another source of destruction of the steam, viz. the cooling of the cylinder by the external air, which would produce an internal condensation whenever steam entered it, and which would be repeated every stroke; this was proposed to be remedied by an internal cylinder containing steam, surrounded by another of wood, or of some other substance which would conduct heat slowly.

"When once," says Mr. Watt, "the idea of the separate condensation was started, all these improve-

Manufac-
tures.

These new
ideas sub-
mitted to
experiment

ments followed as corollaries in quick succession, so that in the course of one or two days, the invention was thus far completed in my mind, and I immediately set about an experiment to verify it practically. I took a large brass syringe $1\frac{3}{4}$ inches diameter, and ten inches long, made a cover and bottom to it of tin plate, with a pipe to convey steam to both ends of the cylinder from the boiler; another pipe to convey steam from the upper end to the condenser; and in order to save apparatus, I inverted the cylinder, I drilled a hole longitudinally through the axis of the stem of the piston, and fixed a valve at its lower end, to permit the water which was produced by the condensed steam on first filling the cylinder to issue. The condenser used upon this occasion consisted of two pipes of thin tin plates, ten or twelve inches long, and about one-sixth inch diameter, standing perpendicular and communicating at top with a short horizontal pipe of large diameter, having an aperture on its upper side, which was shut by a valve opening upwards. These pipes were joined at bottom to another perpendicular pipe of about an inch diameter, which served for the air and water pump; and both the condensing pipes and the air pump were placed in a small cistern filled with cold water."

The steam pipe was adjusted to a small boiler. When steam was produced, it was admitted into the cylinder, and soon issued through the perforation of the rod, and at the valve of the condenser. When it was judged that the air was expelled, the steam cock was shut and the air-pump piston rod was drawn up, which leaving the small pipes of the condenser in a state of vacuum, the steam entered it and was condensed. The piston of the cylinder immediately rose and lifted a weight of about 18 pounds, which was hung to the lower end of the piston rod. The exhausting cock was shut, the steam was readmitted into the cylinder, and the operation was repeated, the quantity of steam consumed and the weights it could raise were observed, and, excepting the non-application of the steam case and external covering, the invention was complete in so far as regarded the savings of steam and fuel.

A large model, with an outer cylinder and wooden case, was immediately constructed, and the experiments made with it served to verify the expectations the inventor had formed, and to place the advantage of the invention beyond the reach of doubt. It was found convenient afterwards to change the pipe condenser for an empty vessel, generally of a cylindrical form, into which an injection played, and in consequence of there being more water and air to extract, to enlarge the air pump.

"The change was made, because, in order to procure a surface sufficiently extensive to condense the steam of a large engine, the pipe condenser would require to be very large, and because the bad water with which engines are frequently supplied, would crust over the thin plates, and prevent their conveying the heat sufficiently quick. The cylinders were also placed with their mouths upwards and furnished with a working beam and other apparatus, as was usual in the ancient engines; the inversion of the cylinder, or rather of the piston rod, in the model being only an expedient to try more easily the new invention." The immense importance of this discovery will form an ample apology for the preceding long description and quotation. It is gratifying to enter the workshop and laboratory of such a distinguished practical philosopher, to be made familiar with his thoughts, to see all his difficulties, and witness his in-

genuity in overcoming them; and although we may Machinery. not be able to do so in reality, we may in imagination, while reading the plain unsophisticated statement of this celebrated mechanic, which contains a complete developement of the steps of his improvements, although there was still required the exercise of further ingenuity to put them into the best form for general practice.

(168.) He now, 1769, took out his first patent embody- Mr. Watt's first patent. ing these several inventions expressed in very general and concise terms, entitled For Methods of lessening the Consumption of Steam, and consequently of Fuel, in Fire Engines, as follows: "First that vessel in which the powers of steam are to be employed to work the engine, which is called the cylinder in common fire engines, and which I call the steam vessel, must, during the whole time the engine is at work, be kept as hot as the steam that enters it: first, by enclosing it in a case of wood, or any other materials that transmit heat slowly; secondly, by surrounding it with steam or other heated bodies; and, thirdly, by suffering neither water nor any other substance colder than the steam, to enter or touch it during that time. Secondly, in engines that are to be worked wholly or partially by condensation of steam, the steam is to be condensed in vessels distinct from the steam vessels or cylinders, although occasionally communicating with them; these vessels I call condensers and, whilst the engines are working, these condensers ought at least to be kept as cold as the air in the neighbourhood of the engines, by application of water or other cold bodies. Thirdly, whatever air or other elastic vapour is not condensed by the cold of the condenser, and may impede the working of the engine, is to be drawn out of the steam vessels or condensers by means of pumps wrought by the engines themselves, or otherwise. Fourthly, I intend in many cases to employ the expansive force (pressure) of steam to press on the pistons, or whatever may be used instead of them, in the same manner as the pressure of the atmosphere is now employed in common fire engines. In cases where cold water cannot be had in plenty, the engines may be wrought by the force of steam only, by discharging the steam into the open air after it has done its office. Fifthly, when motions round an axis are required, I make the steam vessels in form of hollow rings or circular channels, with proper inlets and outlets for the steam, mounted on horizontal axles like the wheels of a water-mill; within them are placed a number of valves that suffer any body to go round the channel in one direction only; in these steam vessels are placed weights so fitted to them, as entirely to fill up a part or portion of their channels, yet rendered capable of moving freely in them by the means hereinafter mentioned or specified. When the steam is admitted in these engines between these weights and the valves, it acts equally on both, so as to raise the weight to one side of the wheel, and by the reaction on the valves successively, to give a circular motion to the wheel, the valves opening in the direction in which the weights are pressed, but not in the contrary: as the steam vessel moves round it is supplied with steam from the boiler, and that which has performed its office may either be discharged by means of condensers, or into the open air. Sixthly, I intend in some cases to apply a degree of cold not capable of reducing the steam to water, but of contracting it considerably, so that the engines shall be worked by the alternate expansion and contraction of the steam. Lastly, instead of using water to render the piston or

Manufac-
tures.

other parts of the engines air and steam tight, I employ oils, wax, resinous bodies, fat of animals, quicksilver, and other metals in their fluid state.

"Be it remembered, that the said James Watt doth not intend that any thing in the fourth article shall be understood to extend to any engine where the water to be raised enters the steam vessel itself, or any vessel having an open communication with it."

This specification, as has been before observed, is very comprehensive; it embraces the grand idea of condensing in a separate vessel called the condenser to be kept always cold, of working the engine by steam, thereby keeping the cylinder always hot. It proposes to work by the expansive power of steam; but it is perhaps doubtful whether this means what is now called working expansively, as this was embraced in a subsequent patent; the high pressure engine is also included, although, as we have seen, (Art. 155.) this had been before proposed by Leupold. Other principles of working rotatively, &c. are included, but as these never have been made to succeed well, any further notice of them is unnecessary.

Conversion
of the reci-
procating
into a circu-
lar motion
to drive
Machinery.

(169.) The rotary principle not succeeding, Mr. Watt's next idea seems to have been to convert the rectilinear and reciprocating motion of the piston into a rotary motion. This had been before attempted by Halls, as we have already described, (Art. 156.) by Fitzgerald, and by Steward, in the year of the above patent, 1769, and subsequently by Steed in 1781; for the simple crank now universally adopted, and which, considering the very common use of this method in the turning lathe, and even in the razor-grinder's wheel, seems most unaccountably to have been overlooked by Mr. Watt. It is indeed said that he had been making experiments on the use of the crank; that these experiments were made known to Mr. Steed, who immediately took out his patent, and thereby prevented Watt from so doing. This patent, however, was not granted till 1781, twelve years after the above patent, the loss of which time appears certainly rather unaccountable. At all events, in 1781, Watt obtained a second patent, in which great ingenuity is exercised in obtaining a rotary motion without interfering with other patents for this purpose; and, although five distinct methods are proposed, amongst which is the sun and planet wheel, not one of them is so simple and advantageous as the simple crank of Steed. And it would certainly have been a more gratifying task to the historian to have had in this place to say, that Mr. Watt had adopted this method by giving a due compensation to the patentee, than to record the efforts of his genius, exercised merely for the purpose of excluding an ingenious rival from participating in the glory and advantages of his construction. If it be true, indeed, that Steed obtained his patent clandestinely, this may afford some apology; but the interval, as we have said above, was very considerable between 1769, the date of Watt's first patent, and that of Steed's in 1781. However this may be, Mr. Watt's second patent, taken out the same year as Steed's, embraced five different methods of producing rotation, of which the sun and planet wheel was one, and was employed by him for several years, till the crank patent expired.

Hornblow-
er's patent.

(170.) In this same year 1781, a patent was obtained by a very ingenious mechanic, Jonathan Hornblower, of Penryn, Cornwall, for a mode of applying expanding steam, by employing two cylinders, by the use of which the force of the apparatus is more nearly equalized.

This has been the basis of several improvements of the first importance in the introduction of double cylinder engines. The following specification is given in the author's own words.

"First I use two vessels in which the steam is to act, and which in other steam engines are called cylinders. Secondly, I employ steam after it has acted in the first vessel to operate a second time in the other, by permitting it to expand itself, which I do by connecting the vessels together, and forming proper channels and apertures, whereby the steam shall occasionally go in and out of the said vessels. Thirdly, I condense the steam, by causing it to pass in contact with metallic substances, while water is applied to the opposite side. Fourthly, to discharge the engine of the water employed to condense the steam, I suspend a column of water in a tube or vessel constructed for that purpose, on the principles of the barometer, the upper end having open communication with the steam vessels, and the lower end being immersed in a vessel of water. Fifthly, to discharge the air which enters the steam vessels with the condensing water or otherwise, I introduce it into a separate vessel, whence it is protruded by the admission of steam. Sixthly, that the condensed vapour shall not remain in the steam vessel in which the steam is condensed, I collect it into another vessel, which has open communication with the steam vessels, and the water in the mine, reservoir, or river. Lastly, in cases where the atmosphere is to be employed to act on the piston, I use a piston so constructed as to admit steam round its periphery, and in contact with the sides of the steam vessel, thereby to prevent the external air from passing in between the piston and the sides of the steam vessel."

This method of working possesses many advantages, but, unfortunately for the inventor, he could not avail himself of them, because the improved mode of condensation which was essential to its operation remained the right of Boulton and Watt.

(171.) While we are speaking of this ingenious idea of Hornblower, it will be well also perhaps to record some further efforts of his genius, although they were of some years later date than that we are at present arrived at. These relate to two different methods for which he obtained patents for producing a rotary engine, or one which should communicate rotation from its first action. His first was a very ingenious but complicated Machine the patent for which is dated 1798. The second was more simple; it was secured by a patent in 1805. It consists of four vanes revolving in a cylinder round its axis. The vanes are like those of a smoke-jack, but of thickness sufficient to form a groove in their edges, to hold stuffing for the purpose of making them steam tight in their action. They are mounted on an arbour which has a hollow nave in the middle. Into this nave the tails of the vanes are inserted, and each opposite vane affected alike by making a firm connection with one another; so that if the angle of one of the vanes with the arbour be altered, the opposite one will be altered also, and the opposite ones are set at right angles to each other; wherefore when a vane is flatly opposed to the steam, the opposite vane will present its edge to it, and this they are constantly doing in their rotation on their common arbour. Hence the steam acts against the vane on its face for about a quarter of a circle, or ninety degrees, in the cylinder where it is destined to act; and as soon as it has gone through the quarter of the circle, it constantly turns its edge to the steam, while at the same

Machinery.

Hornblow-
er's rotary
engine.

Manufac-
tures.

instant another vane has entered the working part of the revolution, and the rotation proceeds without interruption. This engine was to be furnished with the condenser and discharging pump of Watt, but Hornblower added what he considered an improved method of discharging the air from the condenser.

It is easy to show that the friction, and other sources of loss of power, are much greater in the rotary than in the rectilinear action of the steam, while the loss by rendering a reciprocating motion rotary is very small; but this is noticed as one of the most simple combinations proposed for a rotary engine.

Mr. Watt's
patent,
1782, for
double act-
ing engine,
and for
working ex-
pansively.

(172.) It has been thought convenient to collect into one series the three distinct patents of Mr. Hornblower, although it was necessary in order to do so to anticipate by some years the thread of our history. We must, however, now retrace our steps, commencing with an account of Mr. Watt's patent, registered in 1782, embracing various methods of applying steam. First for an expansive engine with six different contrivances for equalizing the power. Secondly, the double pressure or double power engine, in which the steam is alternately made to press on each side of the piston, while a vacuum is formed on the other. Thirdly, a new compound engine, or method of connecting together the cylinders and condensers of two or more distinct engines, so as to make the steam which has been employed to press on the piston of the first, act expansively upon the piston of the second, &c., and thus derive an additional power to act either alternately or conjointly with that of the first cylinder. Fourthly, the application of toothed racks and sectors to the end of the piston or pump rods, and to the arches of the working beams, instead of chains. Fifthly, a new reciprocating, semirotative engine, and a new rotative engine or steam wheel.

Working
expan-
sively.

Of these six divisions of the patent, the two which refer to working by expansion and the double action on the piston are by far the most important. It has been observed that the expression "of working by the expansive power of steam" occurs in the first patent; but it was not put in practice till 1778. In this patent this is proposed to be done in three different ways: first by gradually opening the regulating valves, which admit the steam to act on the piston, and letting it continue so to open during the whole length of the stroke; secondly, by letting them open fully at first, and shutting them completely when the piston has proceeded only part of its stroke; or, thirdly, by the use of a throttle valve placed in the pipe, which, acting in the same manner as the floodgate of a mill, admits no more steam than gives the desired power. The second of these methods is decidedly the best, and, as above stated, consists in shutting off the further entrance of steam from the boiler, when the piston has been pressed down in the cylinder for a certain proportion of its total descent, and then leaving the remaining part of the stroke to be accomplished by the expansive force of that steam which has been already introduced into the cylinder. This gives the means of regulating the acting force of the engine; because the pin of the frame, called the plug frame, which opens and shuts these valves, can be placed in such a manner, that the steam valve shall be shut when the piston has descended one-half, one-third, one-fourth, or any other proportion or part of the stroke; and so far the cylinder will be occupied with steam of the same elasticity as that in the boiler, which is usually a little in excess of that of the atmosphere. In order to press the

piston further down, the steam must expand; and though its elasticity is thus diminished, it will be enough to complete the stroke. It is plain that this can be done in any degree at pleasure, as the adjustment of the pins in what is called the plug frame can be varied in an instant; and, according as the engine requires more or less power, allow the steam to act with its full force upon the piston for a greater or less portion of its total descent. If this method of working an engine had no other advantage than the regulation of the power, it would not effect the end better than the throttle valve; but by the expansive principle a great saving of steam is made. It has been observed of Newcomen's engine, that the motion of the piston is accelerated in its descent by the continued action of the pressure of the atmosphere while the load is constant, or even greater at first. Mr. Watt's engine is the same, but in a less degree, when it has a throttle valve, because the steam cannot then come to the piston, except in a limited quantity; but when the top of the cylinder is open to the boiler, or the throttle valve fully open, the effect is the same as if the atmospheric air had free entrance into the top of the cylinder. Now by stopping the further entrance of the steam at a certain portion of the stroke, the piston can be made to descend with an uniform velocity, by the expenditure of only a portion of that quantity of steam which would be required, if steam of its full density were employed to press it down to the bottom with an accelerated velocity.

Machinery

But when the steam is shut off at a portion of the stroke, the pressure on the piston is continually diminished as the steam becomes more and more rare; and, consequently, the motive force which works the engine diminishes. The motion of the piston, therefore, will no longer be uniformly accelerated, but will approach towards uniformity, or it may even be retarded; because, although the pressure on the piston at the beginning of the stroke may exceed the resistance of the load, yet when the piston is near the bottom, the diminution of the pressure may occasion the resistance to exceed the pressure; in this case the motion can only be continued by the momentum of the moving parts. Whatever may be the law by which the pressure on the piston varies, it is possible to contrive the connecting Machinery in such a way, that the chains or rods at the outer end of the beam shall continually exert the same pressure to lift the pump rods, or that the Machinery shall vary its force according to any law which is found most convenient. This may be done on the same principle that the watchmaker, by the form of the fusee, transmits an equal pressure to the wheel-work, from a very unequal action of the main spring. In like manner, by making the communication from the piston rod to the pump rod by means of chains, which wind upon arch heads, formed to portions of a proper spiral instead of a circle, the force of the piston upon the beam and pump rods can be regulated at pleasure, so as to produce an uniform effect.

(173.) In the preceding Chapter on steam, (Art. 142.) we have given Mr. Davies Gilbert's investigation of the effect of expansive working, and have shown, that if that part of the stroke during which the steam continues its full action be denoted by 1, and the remaining part of the stroke by n , the efficiency of the power on the whole stroke will be $\text{hyp. log. } (1 + n)$; the efficiency, therefore, increases as n increases, and is infinite when n is infinite. It must be observed, however, that in this reckoning an

Manufac-
tures.

The double
acting prin-
ciple.

important element, time, is omitted, and although, according to the method of estimating the efficiency of an engine in Cornwall, the consumption of fuel is the only criterion, yet in general practice time is important, as is also the length of the stroke, which cannot conveniently exceed a certain quantity. We cannot, therefore, attempt to settle such questions by the fluxional or differential calculus. It is sufficient to say, that long practice has proved the value of this part of Mr. Watt's patent, and that it is universally adopted.

(174.) Of the double acting principle, up to this time every engine, whether atmospheric, or a steam engine properly so called, because the piston is propelled by steam, were only what is now called single acting engines; that is, the piston, after having completed the working or down stroke, returned inefficient to the top to be again depressed; but, by this new contrivance, the same cylinder was rendered capable of doing double the quantity of work in the same time, the steam pressure acting and the condensation taking place both during the ascent and descent of the piston. This change was very simple, but very advantageous. It renders the power nearly uniform, diminishes the proportion of cooling surface, a less boiler is necessary, and it reduces the bulk and weight of the engine, the power remaining the same. Another step was still wanting to complete the mechanism of the double acting engine, namely, a guide for the piston rod; and this appears to have been first accomplished in 1784, by the invention of what is called the parallel motion. This is an ingenious combination of levers, (explained in a subsequent article,) one point of one of the levers describing nearly a straight line, to which point the piston rod is connected, so that its rectilinear motion causes the beam to vibrate. This Mr. Watt secured by patent in 1784, and at the same time the following other inventions; viz. first, a new rotative engine, in which the steam vessel was to turn upon a pivot, and be placed in a dense fluid, the resistance of which to the action of the steam was to cause the rotary motion. Second; an improved method of applying the steam engine to the working of pumps or other alternating Machinery, by making the rods balance each other. Third; a new method of applying the power of steam engines to move mills, which require to have many wheels moving round in concert. Fourth; a simplified method of applying the power of steam engines to working of heavy hammers or stampers. Fifth; a new construction and mode of opening the valves. Sixth; an improved working gear; and seventh, a portable steam engine and Machinery for moving wheel carriages.

Another patent was obtained by Mr. Watt in 1785, for a method of constructing furnaces, in which the best principles philosophy could furnish, are applied to elicit the heat, and consume the smoke of the fuel. He also applied to the steam engine the conical pendulum or governor, (Art. 69.) the steam gauge, the condenser gauge, and a useful little instrument for ascertaining the state of the steam in the cylinder, called an indicator.

We have now run through an account of all Mr. Watt's ingenious contrivances, but only barely noted those, by far the greater number, which have found no application either in his own hands nor in those of others; the rest are of the highest importance, and are accordingly stated in greater, and it is hoped in sufficient, detail. It remains now to exhibit his engine, and to explain many of the particulars above verbally stated, by diagrams, indeed, they cannot be properly understood without them,

and which will complete what may properly be considered a second epoch in the history of this noble Machine.

(175.) Mr. Tredgold, in concluding the short account he has given of Mr. Watt's inventions, passes him in review as an author, observing, that "the only part of the theory of the action of steam which Mr. Watt attempted to investigate from first principles is the power it affords by expansion, and this is done imperfectly. The proportions and mode of construction he adopted, seem to have been obtained wholly from trial, and the natural consequence was, a long delay before he brought his engine into use; for though his facility of invention must have been considerable, his means of judging of the value of his combinations were very limited; indeed, he appears to have possessed no other certain test than the expensive and slow mode of proving each by making models and trial Machines. On the ground of not having been remunerated for these expensive trials, he got the term of his patent extended to 1800; and, in consequence, with his partners, made a rapid fortune. He devoted a considerable portion of the latter part of his life to Chemical Philosophy, and particularly its application to the Arts. As an author, he has contributed on the steam engine only some historical notices of his own inventions, a few corrections of Dr. Robison's article in his *Mechanical Philosophy*, and notes to it containing his experiments on the latent heat and elastic force of steam, not given in detail to the world till they were rendered unnecessary by the inquiries of others."

The share which Boulton had in the improvement and introduction of the steam engine must not be forgotten; for, as it has been remarked by Baron Dupin, "Watt's engine was, when invented by him, but an ingenious speculation, when Boulton, with as much courage as foresight, dedicated his whole fortune to its success." He did not hesitate even when Smeaton declared his conviction that it could never be generally applied as a useful agent. Besides, Boulton rendered no small service to Watt and to Great Britain when, by his extraordinary talents in Manufactures and Commerce, he exempted his partner from all the cares of life, from all commercial speculations, and from all those difficulties which are the inevitable consequences of great enterprise in trade. Boulton did still more; he triumphed over all those interests and prejudices which necessarily arose in the beginning to retard the success of the new steam engines and their application." "Men," continues Dupin, "who devote themselves entirely to the improvement of industry, will feel in all their force the services that Boulton has rendered to the Arts and Mechanical Sciences, by freeing the genius of Watt from a crowd of extraneous difficulties which would have consumed those days that were far better dedicated to the improvement of the useful Arts."

In paying this compliment to the well-directed spirit of enterprise on the part of Mr. Boulton, we ought not to pass over in silence the equally meritorious, although less successful scientific adventurer, Dr. Roebuck, who was Mr. Watt's first associate. It was this gentleman who established the iron works at Carron; and he and Mr. Watt proposed establishing an extensive manufactory for steam engines, under Mr. Watt's first patent; and, in fact, the first real engine having a cylinder of eighteen inches diameter was begun by them at Kinneil, near Burrowstowness, at which latter place Dr. Roebuck had immense coal and salt works, which

Machinery.

Manufactures.

not proving successful, he parted with his interest in Mr. Watt's patent to Mr. Boulton. He was, however, amongst the first to appreciate the value of the invention, and supplied the funds requisite for the first attempts.

The preceding notices may be said to complete the history of the steam engine to about the year 1800, since which time no new principle of action has been introduced; although not only have many important improvements been made in the working parts, retaining the engine nearly in the form it had been brought to by Watt, but some considerable changes in its mode of action also have been made by other ingenious men, one or two of which it will be well to describe in this place before we undertake to illustrate the modern engine: but as these are not very commonly adopted, we must content ourselves with a simple verbal description, notwithstanding their ingenuity would fully entitle them to graphic illustration, if our limits would admit of it.

Cartwright's engine.

(176.) *Cartwright's engine* is the first that claims our attention, not only in point of date, being projected in 1797, but also as regards simplicity; it likewise possessed the novelty of being worked by a metal piston, and of returning the whole of the fluid of condensation to the boiler; this fluid having been at first designed to be spirit of wine. The condensation was effected by passing the steam between two large iron cylinders, the inner one being open at its ends, whereby the whole surface of the two cylinders was exposed to cold water: the space between the two being of course closed, except having two valves, one for the admission of the steam and the other for the eduction of the condensed fluid which was drawn from it by a pump, and returned to the boiler. The cylinder, with its piston, was placed over the condensing cistern. The engine was single acting, receiving its steam at the top, and was at bottom open to the cylindric condenser. When the piston arrived at the bottom of its stroke, a passage was opened by a valve in the piston, which placed it in equilibrio in respect of pressure; it now returned to the top of the cylinder, the induction and eduction valves were again opened, and the stroke repeated.

The method adopted for giving the rotary motion was also extremely simple: the piston rod having been made to act on a double crank placed immediately above it, whence rotation was produced by precisely the converse action of the motion described in Art. 77. See also pl. iv. fig. 9.

Woolf's engine.

(177.) *Woolf's engine*.—The mode of condensation invented by Watt being now (1804) become, by the expiration of his patent in 1800, public property, and Hornblower's patent having also ceased, Mr Woolf adopted the arrangement of the latter, with the alteration of using high pressure steam in the small cylinder, and employing the condensing apparatus of Watt. But a change of the working force of steam would have been too slight a ground to have claimed a patent upon, and therefore he commences the specification by a claim to the discovery of a new law of the expansibility of steam. This law of expansibility he stated with great confidence as the result of experiments, in which, however, he had no doubt deceived himself. This assumed law is, that steam generated at any number of pounds per inch above the atmospheric pressure, will expand to an equal number of times its volume, and will be then equal in elastic force to the atmosphere, the temperature being unaltered. Hence steam generated at forty pounds on the square inch above the atmosphere, was expected to ex-

VCL. VII.

pand to forty times its bulk, and still be equal to the atmospheric pressure. Machinery.

This is clearly erroneous; for if even the latent heat of steam were the same at all densities and temperatures, it is obvious that the elastic force of steam at forty pounds above the pressure of the atmosphere is, reckoning that pressure at fourteen pounds, equal in all to fifty-four pounds, and consequently the elastic force after expanding forty times will be but 1.35 pounds per inch instead of 14; and even with an expansion of four times instead of forty, its force would be scarcely equal to the amount stated.

It must be admitted, however, although the inventor was mistaken in this estimate, that, as we have seen in the Chapter on steam, the elasticity of this vapour increases in a much higher ratio than the temperature; and if, therefore, equal degrees of heat could be obtained with equal quantities of fuel, that is, for example, if steam at 220° in contact with water could be raised to 230° with the same consumption of fuel as would raise steam from 210° to 220°, and again that its expansion followed the law last stated, there would still be a great saving by employing Woolf's engine; and even notwithstanding this may, and certainly does, not obtain to its full proportion, yet it may in part, and indeed the engine is generally said to possess some advantages.

To attempt any account of the numerous patents and propositions for real or supposed improvements in the steam engine from the year 1800 to the present time would require a volume of itself. The immense national importance of this engine, its application to navigation, to rail roads, and common road locomotive carriages, &c. seemed to offer favourable opportunities to speculators to secure to themselves the advantages of some real or supposed saving, or to obtain the monopoly of some particular construction; and accordingly for several years our patent lists were crowded with specifications of this kind, many of them certainly containing great improvements, but others serving little other purpose than that of putting fees into the pockets of the several parties attached to the patent offices.

Description of the Modern Steam Engine and Improvements. Machinery

(179.) We have brought up the history of the invention of the steam engine to the termination of Watt's extended patent, from which time we may almost date a new epoch in its progress of improvement; for since that time there has been nearly a total change in the manner of constructing, arranging, and putting together the several parts of the engine, and many advantageous alterations have been made as far as respects the durability and accurate performance of the Machine; although little has been added in point of principle, if we except the second cylinder of Hornblower and Woolf, which has been concisely described in a preceding page, although, for the sake of connection, misplaced in point of date. The high pressure engine likewise, although included in Watt's patent, was not reduced to a proper working form till some years after its expiration; this still remains to be described in a subsequent section.

It would certainly be interesting, if the nature of this Work admitted of it, to show by a series of plates the successive steps which have been made in the progress of this engine from the earliest of Watt's construction to the present time; we should then have to exhibit the large heavy wooden beam with arched heads and chains; or the piston rod with ratchet teeth, and corresponding teeth in the arch head, the sun and planet wheel for producing rotation, and other constructions now wholly laid aside.

This extension of our Essay, however, is inadmissible; and we must, therefore, proceed to describe the modern engine, in which all the principles of Watt have been retained, but the arrangements, proportion of parts, and working gear largely improved by the experience, ingenuity, and better workmanship of later masters. Even of these changes we can attempt the description of only a few of the best, for the variations are nearly as numerous as the engines themselves. We have mentioned Watt's patent for a parallel motion; we have now parallel motions of every variety. Watt placed his cylinders vertically; we have had them since placed horizontally, inclined, and inverted. Watt made his pistons steam tight by packing with hemp; we have had since spring pistons, revolving pistons, metal expanding pistons, &c. The cylinders, besides the particular positions in which different inventors have placed them, have gone through every variety of proportion, a like variety has been tried in the relative proportions of the condenser and air pump, as compared with the cylinders; and the forms of the valves, and the methods of opening and closing them for the admission or eduction of steam to and from the cylinder, &c., have gone through perhaps a greater change than any of the other parts alluded to. But of all the changes which have taken place that of improved workmanship is the most important, which is now very superior to what it was some years back; and to this, perhaps, more than to the change in the actual arrangements, is to be attributed the increased and still increasing power of the steam engine. Hence in the illustrations which are about to be given, the reader should consider only the principle of the engine to be due to Watt, the working parts must be looked upon as resulting from the accumulated ingenuity of all, or of many, of the most distinguished engineers whom England have produced during the last forty years, Watt himself

Introductory remarks to the description of the modern engine.

Changes in the working

Manufactures.

being of the number; many improvements being due to him since the expiration of his patent.

Description of the several Parts of the Modern Steam Engine.

(180.) In order to render the description of the steam engine in its present improved form more intelligible to the general reader, we propose, first, to describe separately the different parts of it which are essential to fully understanding its action, although it will not of course be expected that we can enter into a minute detail on some minor points. A few of the working parts, however, require particular illustration: such as the contrivance for producing a parallel motion, the nature and action of the steam valves, the steam pipes, pistons, cylinders, &c.; these will be found described in the following articles.

Description of the boiler.

(181.) *Of the boiler.*—The boiler, as well from the nature of its duty as from the several self-adjusting apparatus attached to it, calls first for our attention. It will be seen in a subsequent section, indeed it has been shown in Art. 66, that by means of the fly wheel and governor, the speed of the engine may be rendered uniform under various degrees of resistance; but it follows, of course, that when the speed is thus uniform, and the resistance greatly diminished, if the same quantity of steam continued to be generated, it would, for want of the usual demand, increase in density and elasticity, and, without some provision to meet such a case, burst the boiler. This renders it necessary to provide a *safety valve*, which is a common appendage to all boilers. This safety valve allows the overplus quantity of steam to escape; but here again is another evil, unless provided against, *i. e.* the unnecessary destruction of fuel and waste of power. For the prevention of this, the *self-acting damper* has been invented: this, by the means hereafter explained, is so adjusted that when the action of the steam is too great, the damper descends and checks the power of the furnace, and when too small, the damper, by rising, increases its draught and intensity of action. To some boilers are also attached self-adjusting feeders to supply the fuel to the furnace, in which case the feeder is also regulated by the same apparatus which acts on the damper. To some also are attached internal safety valves, to guard the boiler from the effect of external pressure in case of any sudden or unusual condensation of the steam in the boiler.

The *feed pipe* is another attachment likewise self-acting. The demand for steam, as we have seen, is uncertain; the supply of water required, therefore, is also uncertain, and if thrown in by any constant force or pressure would, in some cases, overcharge the boiler with water, and in others allow it to fall so low as to expose the sides and flues to the action of the fire without a proper conducting body to take off the heat, and thereby not only burn and destroy the metal, but lay the foundation for the most serious accidents. Boilers again are supplied with *gauge cocks* with pipes descending into them, to such depths that one of them opens just above the proper surface level of the water, and the other just below it, so that when the water is in proper quantity and the first of these cocks is turned it will yield steam, and the other being turned it will yield water; but if the water is too high in the boiler both pipes will be immersed in, and will give out water, and if too low they will both give steam; the engineer, therefore, by this means, has it always in his power to ascertain the state of his boiler, and whether or not the self-acting feeder is

properly performing its duty. Another attachment to the boiler, or to some pipe in its immediate vicinity, and in connection with it, is the *barometer gauge*, by means of which the elastic power of the steam may be seen at any moment by inspection. These several parts require some explanation, which is given in a subsequent page. At present we shall offer a few rules and remarks relatively to the proper size and figure of the boiler, and the proportional part of its whole capacity which ought to be appropriated to the water and steam.

(182.) *Dimensions of low pressure boilers.*—The pressure per square inch on the piston of course varies in different engines, yet there is a sort of medium pressure generally aimed at, which may be taken at about eight or ten pounds per square inch, after all deductions for friction, air pump, &c.; and as the motion of the piston is also generally about 220 feet per minute, we have 33,000 pounds (the horse power) divided by 220, equal to 150 pounds, or to fifteen inches on the piston for every horse power, when the pressure is ten pounds.

Machinery

Dimensions of low pressure boilers.

$$\text{Hence } \frac{15}{144} \times 10 \times 220 \times 60 = 1375 \text{ cubic feet of}$$

steam employed for every horse power per hour; if to this we add a certain loss of steam at the several valves, &c., and considering 10 pounds per inch as rather on the maximum side, it may be assumed that every horse power requires about one cubic foot of water per minute; for we have seen that where extreme nicety of experiment has been had recourse to, a cubic foot of water will form only about 1711 cubic feet of steam. The assumption, therefore, of one cubic foot of water per hour for each horse is sufficiently accurate for our purpose.

Now the boiler must obviously contain as much steam as will supply the engine at each stroke, with but inconsiderable decrease in its elastic force, and the space will therefore depend on the manner the steam is supplied. If it be admitted to the engine only a part of the time of the piston's descent, there must be so much steam that the use of the quantity required may not lessen its elastic force. If the steam be generated equally, and the space for it only equal to the quantity consumed at each stroke, and all the quantity be wanted during the stroke of the piston, the elastic force in the boiler would vary one half, and the loss of effect would be very considerable. This practice is of course inadmissible in low pressure engines, and generally from five to eight times the quantity used at each stroke should be already existing in the boiler. Dr. Young in one place, without specifying any particular case, says that ten times the volume is sometimes provided. Another practical rule has been given which, however, like the former, seems very uncertain, this is, that every horse power requires 25 cubic feet space in the boiler; others say 20, and, in some instances, it has been stated that as little as 8 cubic feet per horse power have been found sufficient. In land engines, however, the boiler is generally rather larger than real practice requires, so that few fixed and determinate dimensions can be given. The boiler of a 10-horse power engine in His Majesty's Dock-yard at Woolwich is 9 feet long, 4 feet 10 inches deep, and 4 feet 3 inches broad, of which depth 3 feet 9 inches is intended to be occupied by water. The top of the boiler is semi-cylindrical, and the bottom is also partly cylindrical or concave, both concavities being downwards. Another boiler, called a 30-horse boiler, intended to supply two

Manufac-
tures.

14-horse engines, of a similar form, but with a central flue, has its dimensions as follows: length 15 feet, breadth 5 feet 6 inches, and depth 7 feet 6 inches, depth of water 4 feet 9 inches.

In the former the cubic content is about 200 feet, which is 20 feet per horse, and the steam space rather less than a third of the whole, viz. about 60 feet. The capacity of the cylinder or cubic feet of steam used at each stroke 6.8 feet; the steam space, therefore, in this case is between eight and nine times the quantity demanded at each stroke.

In the second boiler, after deducting the flue, the capacity is 465 cubic feet, or $15\frac{1}{2}$ times the horse power, and the steam space about $4\frac{1}{2}$ times the demand for each stroke.

These are two practical examples, but many others might have been given, which would have brought out different proportions. In general, however, some tolerable approximation to what is above stated may be considered as the usual practice.

(183.) The boiler above described has, as we have seen, a semi-cylindrical top, and concave bottom and flue, in other cases the bottom and sides are plane, and very commonly the whole boiler is cylindrical with spherical ends. It does not appear, however, that the form of the boiler is of great importance, but it is very essential, whatever be the form, that a certain proportion of the whole be exposed to the action of the fire. Smeaton was the first who experimented on this subject; and he, from the results of his experiments, constructed a table showing the boiler surface required to be exposed to the effect of the fire and smoke of the fire for atmospheric engines, and the quantity of coals to be consumed per hour. His quantity of surface for one bushel per hour is 88 feet, and for 13 bushels per hour not quite 82 feet of surface per bushel. This is equivalent to 8.2 feet of surface for converting one cubic foot of water into steam at about 220° ; a result which is also verified by Mr. Watt, who says, that with the most judiciously constructed furnaces it requires 80 feet of surface of the boiler to be exposed to the action of the fire and flame to boil off a cubic foot of water per hour. In neither of these cases is there any distinction made between the quantity of surface exposed to the direct action of the fire, that is, to the area of the bottom, and that only exposed to the flame and smoke; but recent observers consider that much depends upon this proportion. In general, however, it may be stated that in common practice from 3 to 5 feet of boiler are appropriated for each cubic foot of water boiled off per hour; but Tredgold states $4\frac{1}{2}$ feet as the proper quantity to be thus appropriated. In the boiler we have described the bottom area scarcely exceeds 3 feet the horse power, and they have always been found to be perfectly efficient.

Some boilers, as we have seen, have central flues, others have only side flues; the one shown in the plate xi. has no central flue, and the progress of the flame and rarefied air is sufficiently obvious. When there is a central flue, the flame, after passing under the boiler, returns through the central flues, passes thence along one of the side flues, traverses the end of the boiler along the other side flue, and then along another flue parallel to the boiler, but not contiguous with it, to the chimney.

Safety of
boilers.

(184.) *On the safety of boilers, and the accidents to which they are liable.*—Steam engines may certainly be considered as the highest effort of human industry, but it is of the greatest importance that they should be safe: unfortunately, we have frequently the most terrific acci-

dents occurring, which it is necessary to guard against and prevent; these are, of course, more common in the boilers of high than of low pressure engines, but they have occurred in both, and the consequences attending them have been very terrible. To devise a sure means of preventing such accidents it must be confessed is a problem that has not yet been completely solved, although it has excited the attention of men of Science and of the most intelligent practical engineers; amongst the former M. Arago has entered upon this inquiry, and has separated these accidents under different heads, and traced them to different causes. The most common accident is when the power of the steam is allowed, either by neglect or design, to accumulate, till, exceeding the strength of the metal, the boiler is destroyed from internal explosion. In general, a proper constructed safety valve is supposed to be a remedy for this evil; but cases have occurred in which the boiler has burst immediately after opening the safety valve, as if the relief given to the boiler had been the cause of the accident, by producing an additional expansive power in the steam.

This appears very extraordinary, *i. e.* that relieving the boiler of a part of its pressure should increase the expansion of the part remaining; the fact, however, has been accounted for by Mr. Perkins as follows. He supposes that in such cases the boiler has not been supplied with sufficient water, and that the part of the boiler immediately above the water becomes red hot; this heat is communicated to the steam, and increases its elasticity, but not according to the laws of elasticity of steam in contact with water, that is, he supposes it to increase its elasticity but not its density; but now the safety valve being opened, the water of the boiler is agitated, the surface water is driven up against the red-hot boiler, its density is thereby suddenly increased to a degree greater than can be sufficiently relieved at the common safety valve, and explosion follows. It has been suggested, however, by Mr. P.W. Barlow, that the latter part of the above hypothesis is not entirely correct; that it is more probable that the water thus driven against the red-hot iron is decomposed, the oxygen being absorbed and hydrogen formed in such quantities as sufficiently to account for all the consequences which follow. The provision against this cause of accident, supposing the above hypothesis or either of them correct, is by paying proper and particular attention to the feeding pipe and apparatus.

Another species of accident which has occurred to steam boilers is when a diminution of elastic force has preceded the explosion. M. Arago has reported some accidents of this kind:—"A boiler," he says, "constructed to produce low pressure steam, exploded in the midst of a manufactory, immediately after a large discharging cock had been opened, through which the vapour began to escape with rapidity. To open a stop cock or raise the safety valve is evidently one and the same thing; the explosion in this case, therefore, was determined by an operation that it would seem ought to have prevented it. This fact," M. Arago observes, "however strange it may appear, must be received with the utmost confidence, when it is stated that I received it from Mr. Gensoul of Lyons, and that this able engineer was an eye-witness of the accident. If in an extreme case, such as that just mentioned, the opening of a valve may bring on the bursting of the boiler, it must frequently happen that such an opening, without occasioning an accident, may, notwithstanding, give rise to a sensible and sudden increase in the elastic force of the vapour."

Machinery.

Manufactures.

The phenomenon within such limits may be studied without danger. I am aware that the experiment has been made at Lyons, and that in a little high pressure boiler, as soon as a discharging cock was opened, the safety valve rose also. M. Dulong and myself have, on the other hand, always observed that a diminution of tension accompanies the opening of the valves. But I do not on that account regard the experiment made at Lyons as less certain, since it has for witnesses M. Tabareau, Director of the School of La Martiniere, and M. Rey, Professor of Chemistry." No probable explanation is here offered by M. Arago; but it would necessarily happen that if any stoppage took place in the feed pipe till the boiler got red hot, as supposed in the last case, and that suddenly this pipe opened, that the introduction of water would first reduce the elasticity of steam, but immediately after the water rising to the red-hot part a sudden expansion or decomposition would take place, and a consequent explosion. Another kind of accident, frequently attended with very fatal consequence, is the collapse of boilers from external pressure. On this head M. Arago observes, "Boilers made of sheet copper or wrought iron, and those in particular that work with low pressure steam, suffer under certain circumstances from accidents precisely the reverse of those we have hitherto spoken of."

These boilers occasionally collapse completely, their sides being suddenly bent or crushed inwards. The cities of Lyons and St. Etienne have recently been the theatres of several accidents of this kind; and it is necessary to be protected against them, were there no other object than to prevent considerable manufactories from being suddenly reduced to a state of inactivity.

The lesser cylinders, which in some cases form internal fire-places and flues, also collapse occasionally. Their sides being unable, under certain circumstances, to resist the pressure contained in the circular space that surrounds them, they give way and flatten suddenly. And as this cannot take place unless the metal gives way in some part, the boiling water spreads in torrents through the adjacent apartments, and often produces serious accidents. Mr. John Taylor, F.R.S. has furnished the following instance of this kind of accident.

At Mold mines, in Flintshire, there is a large steam engine driven by three boilers with internal furnaces. On a certain day the Machine had been stopped for about five minutes; the fireman had already shut the doors of all the three furnaces, closed the dampers of two of the chimneys, and was in the act of closing that of the third, but hardly had the metallic plate reached its place when he saw a gust of flame dart from the fire-place, and an explosion followed instantly. Two workmen who were unfortunately in the direction in which the boiling water was projected were instantly killed.

A close examination of the boiler showed, that the outer cylinder had neither moved from its place nor sustained any damage. Even the weight suspended to the lever of the safety valve was still in its place after the accident. Neither had the less cylinder been moved from its place, but was so flattened by the crushing of its sides, that the hand could not be introduced between the plates.

The proper remedy for this accident is the interior safety valve, as described in a subsequent section.

Other accidents peculiar to boilers with interior furnaces are pointed out by the same author. A little consideration, it is observed, of the numerous causes that may bring about the explosion of a boiler, and on

Machinery
the various combinations of which they are susceptible, will show that it is hardly possible to obtain invariable rules in respect to them. It may, however, be remarked as a general law, that the figure of the boiler is the preponderating cause, and that it is upon it that the species of bursting that takes place most frequently depend. It is in this point of view that detailed and complete accounts of the accidents that daily happen would be of great use. We may now assert, in consequence of the valuable investigations published by Mr. Taylor, that in boilers with interior furnaces or flues passing through them, the surface of the inner cylinders must be considered as the weakest part.

After the almost simultaneous explosion of two boilers at the tin mine Palgooth, it was found that the inner cylinders of both boilers were twisted upon themselves and torn in a great number of places. At the mine of East Erennis, the inner cylinder was not only flattened by the approach of its upper and lower surfaces, but had been thrown out of the building with great force, while the outer cylinder had not been moved from its place or sustained any important injury. We have already mentioned another example still more remarkable, of the complete change of shape and breaking of the less cylinder, while the outer one remained unaffected.

To this list may be added the recent fatal explosions of the Helen M'Gregor on the Ohio, and the Chief Justice Marshall on the Hudson, in both which cases the accident took place at the instant of setting the engine in motion; and in the latter, the safety valve was open, and the steam escaping freely by it.

In a subsequent page we shall give an abstract of a Parliamentary inquiry instituted with a view of devising some means of insuring the safety of steam engine boilers, particularly those employed in steam vessels. At present our object is to describe the several appendages to the steam boiler, of which a general view has been taken in the leading part of this Chapter.

(185.) *Safety valves.*—The external safety valve was first employed by Papin in his digester; it was afterwards adopted by Savery, and is still used in nearly the same form in a great many engines, although various forms have been proposed by different makers. The kind here alluded to is what is called the steel-yard safety valve. The construction is very obvious: a support projects from the side of a short tube, to which a lever is attached, carrying a weight at its other end, and to the lever is fixed the valve which opens when the pressure of the steam from within exceeds that to which the weight is adjusted, or rather to the part of the lever to which the weight is appended. This is theoretically all that is required; but the weight by accident may be displaced, and the valve itself by corrosion may adhere to its seat, or the weight, through the ignorance of strangers, or the daring of the engineer, may be increased; cases which have too frequently occurred, and caused the sacrifice of the lives of a great number of persons. A very melancholy accident of this kind occurred a few years back in one of the boats on the Norwich River, which killed on the spot thirteen individuals, and scalded and maimed many others. This led to a Parliamentary inquiry into the subject, and various contrivances have been had recourse to to prevent the sticking of the valve; for the rest, the only remedy appears to be to have a box or cover over the valve, to be accessible only by the engineer. A different form of safety valve is shown externally in the boiler at W, pl. xi. the steam ascending the rising pipe.

which is carried into the open air; but the steel-yard valve is represented in the internal valve at V.

(186.) *Self-acting feeder*.—This is represented in plate xi. E is a pipe rising from the boiler, having a cistern at its upper part; this cistern is constantly supplied with water by the engine from the hot-water well; at the bottom of the cistern is a valve opening downwards, but which is kept shut, while the boiler has a proper supply of water by the following contrivance. A stud projects above the edge of the cistern, on which is supported a lever carrying a weight at one end while to the other is suspended a small wire rod, which, passing through a stuffing box, descends into the boiler; to the end of this is hung in the water of the boiler, what is called a stone float; that is, a large stone, which is so balanced by the weight as merely to float on the surface of the water, and of course to rise and fall with it. When the water, therefore, sinks in the boiler the stone sinks with it, which raises the balance weight, and with it the feed valve; hence the water in the cistern descends the pipe, and is sometimes carried by it to the bottom of the boiler and along its bottom, in order that it may receive some heat in its passage, before mixing with the general mass. This water, thus supplied, is furnished from the hot well, and generally enters at about the temperature of 100° through the horizontal pipe s s.

(187.) *Self-acting damper*.—This adjustment takes place through the feed pipe, and is thus managed. A central tube rises in the feed cistern, so as to have a way into the feed pipe without deranging the feed valve. In the pipe itself is hung a weight less in diameter than the bore: this weight is suspended by a chain, which, passing over two pulleys, has the damper D hung from its other end, which, working in two iron grooves, is free to ascend or descend. The weight in the tube being such as just to balance it, together with the friction of the chain pulleys, &c. when immersed to a certain depth in the water of the tube, forced up into it above the level of the boiler by the pressure of the steam. Suppose now the damper properly adjusted to the elasticity of the steam, equal to a certain amount of pressure, and that the weight and damper are in equilibrio and at rest. In this state they will remain until some change in the state of the steam arises. Suppose its elasticity to be increased, this will force the water higher up in the tube, the relative gravity of the weight will be diminished, and the damper descends, and thereby checks the draught of the flue, and of consequence the intensity of the fire. On the other hand, if the elasticity diminish, the water sinks, and the weight with it; this rises the damper, increases the draught, and at the same time the combustion of the fuel.

(188.) *The gauge cocks*.—These are represented at Z; their situation, however, is not important. One of these will be seen with its end just above the surface of the water, and if opened will of course furnish only a supply of steam, but the other, if opened, will yield water; therefore when this happens the water is at its proper level; but if both cocks supply water, this is too high in the boiler, and if both yield steam the water is too low, and either circumstance requires the attention of the engineer.

(189.) *Self-feeding furnace*.—We have above described all the usual appendages to a steam boiler, but with all these the furnace still requires the attendance of the stoker, but even the service of this individual has been in great measure dispensed with by one or two very ingenious contrivances. The first was proposed by Mr. Brunton,

a highly ingenious engineer of Birmingham. In this furnace the grate is circular, and is made to revolve horizontally beneath the boiler, by which means the heat is uniformly distributed over the whole of the lower surface, and a regular supply of coals is furnished from a hopper above. To effect this, the axis upon which the grate turns is connected with the steam engine, from which it derives its rotation, and for a cylindric boiler of five feet diameter it is made to perform about one revolution per minute. In its rotation every time it arrives at a certain point, the channel from the coal hopper is opened and a supply of coals is obtained. In order to prevent the air from passing down with the coals into the furnace, the patentee describes in his specification a rim, upon which the regulator is intended to lie descending into a trough, for the purpose of forming a water or sand valve. There is also a regulator to the feeder connected with the damper, so that if the boiler becomes too hot, or the pressure of the steam increase, the quantity to be supplied should be diminished in a proportionate degree.

Another self-acting furnace is likewise sometimes employed; this also has a hopper near the mouth of the furnace, through which coals, first broke down to a proper size, by passing between two rough or studded rollers, fall in a gradual and continued stream; below this aperture in the hopper, and in front of the furnace, are two iron circular plates, revolving with a very great velocity; and as the small lumps of coals fall on these plates, they are cast and scattered over the whole surface, whereby the fire is fed with fuel in a very equal and uniform manner, and by such continuous and small quantities, that much of the smoke which arises in common furnaces is destroyed.

(190.) *Steam gauge*.—To ascertain the pressure of the steam with greater accuracy than can be done by the load on the safety valve, recourse is had to a barometer gauge G, attached either to the boiler or to some tube immediately in its vicinity, and in open connection with it. The usual form of this is that of an inverted syphon or bent tube either of glass or iron, one leg of which is joined to the steam pipe, and the other open to the atmosphere. A quantity of mercury being poured into the tube, it will, when the steam has exactly the same elasticity of the atmosphere, stand at equal height in each leg, these being both in this case subject to equal pressure; but if the elasticity of the steam exceeds that of the atmosphere, the mercury in the steam leg will descend, and that in the opposite leg rise, and the difference between the level of the two will be the excess of the steam pressure above the atmosphere, and half these number of inches will be about the excess in pounds per inch. On the contrary, if the steam is under atmospheric pressure, the difference will be seen by the depression of the mercury in the leg exposed to the atmosphere.

When the tube is of glass, the difference may be read off by looking to the columns themselves, but when of iron, a rod is inserted in the open end, and is graduated above, the rod rising or falling with the mercury. But in this case, the divisions, which are numbered for inches, must be only half inches, because a rising of half an inch in one leg is produced by a corresponding fall in the other leg of the same amount, making one inch difference.

(191.) *Man hole*.—This is an aperture in every boiler large enough to admit a man to descend to clean the boiler or for any other purpose; it is shown in the figure at M, having the internal safety valve V in its surface. This, after cleaning or repairing any internal parts, is securely

Machinery.

Manufactures. fixed down by screws and nuts, and carefully luted all round to render it steam tight. T T is the pipe for conducting the steam to the engine.

Of Steam Pipes and Cylinders ; illustrating the general Principles of Action in Single and Double Acting Engines.

Steam pipes, valves, &c. (192.) It has been stated that great changes have taken place in the construction and arrangement of valves, steam pipes, &c., since the first introduction of the steam engine, properly so called, by Watt, and that there are at present a great variety of forms made use of by different makers. It will not, of course, be expected we should enter into a full description of these matters ; it will, however, be rather interesting to explain one of the earliest methods, although not the best, by which the operation of working the valves was effected ; we shall then show an example or two of the most recent and most improved methods. First, however, as this article is intended to furnish rather a popular description of the steam engine, than an article for practical engineers to consult, we propose to explain the general principle from which the motion is derived.

Steam valves, condensers, and single acting engine. Pl. xii. Fig. 1. Fig. 1. plate xii. represents a section through the cylinder, steam pipe, condenser, air pump, condensing cistern, and hot well, of a single acting engine, viz. an engine in which the piston is only acted upon during the down stroke, being returned from the bottom to the top of the cylinder merely by a counterweight, placed for the purpose on the other extremity of the beam. In this figure C is the cylinder, P the piston, E the steam pipe, B the condenser, A the air pump, K the hot well, H the blow valve, R is the rod of the piston passing through a stuffing box at R, to render the cylinder steam tight ; S is the pipe through which the steam is admitted to the cylinder, and V D the pipe or passage through which it is afterwards passed to the condenser ; G is a passage between the condenser and air pump, in which is a valve G, shutting towards the condenser, and *a*, *b*, *c* are three other valves ; *c* opening or closing the passage between the steam induction pipe S and the cylinder C ; *b* opening or closing the pipe or passage E, which forms a communication between the top and bottom of the cylinder ; and *a* opening or closing the eduction pipe D, by which communication is made between the cylinder and condenser. L is a cock which admits a jet of water into the condenser, and O is a passage by which the condensed steam and injection water is discharged from the pump A to the hot well K, to be from thence, by another pump, returned again to the boiler.

In the position in which the piston is shown, it has just begun its down stroke ; the valve *b* is closed, and *c* open, so that the steam from the boiler is pressing upon the top of the cylinder and carrying it downwards, the valve *a* being up, whereby the steam in the cylinder is open to the condenser ; which, as it rushes in, is immediately condensed, whereby the pressure of the steam above the piston becomes effective, and it would be so to its whole amount if the vapour in the condenser could be entirely annihilated ; but some elasticity always remains in this vapour, and the piston is therefore urged on by a force equal to the difference between the elasticity of the steam and vapour. Conceive, now, the piston to have descended to the bottom of the cylinder, the valve *c* to be closed, thereby intercepting the passage of the steam from the boiler to the cylinder, and at the same

Machinery. time the valve *a* to be closed, and *b* opened, then the communication being opened between the two ends of the cylinder, and the induction and eduction valves being both closed, the piston is in a state of equilibrium, and the counterweight at the other end of the beam will return it to the top of the cylinder ; being arrived there, the induction and eduction valves are opened, and the equilibrium valve *b* is closed, the condensation is renewed, and the piston again descends. The pump A, worked by the engine, continually drawing off the water of condensation, condensing water, and the air brought into the condenser with it.

In double acting engines the condensing jet is constantly playing into the condenser, but in single acting engines it is frequently suspended during the up stroke of the cylinder, in which case the cock L is alternately opened and shut by a part of the working gear. This is sufficient to give a general idea of the nature of the operation in a single acting engine ; but we have said nothing relative to the methods by which the valves *a*, *b*, *c* and cock L are opened and shut, which in their simplest shape become very complicated. If the stroke of the engine could be always maintained of the same length, and the engine were not worked expansively, nothing could be more simple. We have only to conceive the three valves fixed upon one rod, at proper distances, passing through a stuffing box O, and that this rod is lifted and depressed at every stroke, so as alternately to close the valve *b* and open *a* and *c*, and then to close *a* and *c* and open *b*, whereby the action would be continued ; but it is necessary that these valves act independently, and hence arises considerable complication which it will be our object to explain.

(193.) When there are rotary parts in an engine, the Method of opening and shutting the valves is commonly effected by opening and closing the valves. means of eccentrics, but in others by a rod or beam, called a plug tree, which is attached to the engine beam, near to the end moved by the piston rod. This plug tree is provided with adjustable plugs or tappets, as at *f* and *d*, fig. 2, which strike the levers or handles of the valves, and thus open and shut them at the proper intervals as the beam ascends or descends, and these intervals are adjustable to the greatest accuracy, by a corresponding adjustment in the situation of the tappets.

In general, modern engines are furnished with valves, working through stuffing boxes, as shown in fig. 2 ; Fig. 2. but in others, commonly those of earlier date, the stuffing box is in the side, as is described below. As it is most important that the several valves should open and shut at proper times, great attention is paid to this part of the operation. When lifting valves are employed, they are generally opened by weights ; thus a weight *w*, sufficient to overcome the friction and open the valve, acts by a short arm *a* on the axle which requires to be turned to move the valve ; this weight is kept suspended by a spring catch *b* while the valve is closed, and when the catch is disengaged by the handle *c*, being moved by the tappet *d*, the valve opens, which if large requires considerable force acting as it does against the pressure of the steam ; in these cases, however, valves of a particular form, or other means are had recourse to, to facilitate the operation. In some engines the valves are opened as well as shut by the motion of the engine itself, but weights have hitherto been preferred, as they are conceived to open valves more rapidly than when acted upon by the moving gear : it certainly, however, leads to greater complication ; for it is not only neces-

Manufac-
tures.

sary that the weight should open the valve rapidly, but the fall of the weight must be afterwards regulated, at least it is thought to be necessary in many cases. In these it either descends into, or forces a piston into a vessel of water, *c*, while the aperture by which the water escapes from under it may be increased or diminished at pleasure; the weight, therefore, acts with its full weight to open the valve, but as soon after as it begins to move, it is retarded by the water till it is finally stopped, and, during the ascent, a valve opens inwardly at the bottom of the vessel, and, therefore, the engine has no more than the weight to raise again. Our figure and description here have only reference to one valve, but there are three, besides the injection cork, which must be provided for.

The preceding illustration will, however, facilitate the comprehension of the following explanation, in which, to show Watt's early method of working, the valves are represented as turning on axles passing through stuffing boxes in the sides of the vessels, being the actual mode of operation adopted in the single acting engine described in a subsequent article.

A different
method of
working
the valves.
Fig. 3.

(194.) *Steam pipes and valves.*—The cylinder, steam pipe, and valves referred to above are represented in fig. 3, where A is a section of the cylinder, in which the piston H moves, F the steam pipe proceeding from the boiler, and Q the pipe descending to the condenser L. N is the air pump, *m* the passage or pipe from the pump N to the condenser L, in which passage is an occasional communication by a hanging valve at *m*, which shuts towards the condenser; *l* is the injection valve, to be lifted by the engine at every stroke, for the purpose of condensing the steam; *w* is the snifting or blowing valve placed outside the condensing cistern M. This valve communicates with the condenser by a pipe passing through the side of the cistern M. K is the exhaustion valve, to be lifted by the engine, and thus to open a communication between the cylinder and condenser. O is the steam valve, called the equilibrium valve, also to be lifted by the engine, and opening a communication between the upper and lower part of the cylinder through the steam pipe *r*. F is an upper steam valve of the same kind, opening a passage between the boiler and top of the cylinder, and thence by the pipe *r* and valves O K to all parts of the engine.

The valves are lifted by means of a lever applied to each, within the iron box in which it is contained, entering into an opening in the stem of the valve, and a second lever is fixed on the axle of the first on the outside, to be connected with the lever and handles *x*, *y*, *z*, which open and shut the valves. There are three separate axles or spindles placed parallel and above one another, having each a handle as above described, by which it is moved either by hand to start the engine, or by tappets on the plug beam R, when the engine is in action.

The two upper spindles have short back levers pointing towards the cylinder, from which rods are suspended, with a sufficient weight *o* to turn round the spindles and to cause the handles to rise. The lower spindle has also a lever projecting from it, but in an opposite or forward direction, with a heavy weight *n* fixed at its end, which causes the handle to descend. The axles of the lower handles have small levers or catches, fig. *a*, which act in the hooks of a double hatch or detent, which is movable upon a centre pin situated between the two axles. The hooks of this detent are to detain the catches of the spindles, and to prevent the handles *y*, *z* from

Machinery
moving by the weights till the detent is moved on its centre, so as to relieve the catches of the levers from the hooks *t*, *v*; but it is evident that when only one catch is hooked, as 2, by the lower hook *v* of the detent, if the other catch 1 is moved by depressing its handle *y*, it will press the end *t* of the detent forward upon its centre, which at the same time pressing back the hook *v*, releases the catch 2 of the lower handle, and the weight *n* on the spindle immediately falls.

The upper handle is employed to open and shut the valve F, having a lever which communicates, by a rod 2, with the lever 3, so that by pressing down the handle it shuts the valve F. The weight attached to this handle tends to open the same valve, so that when the handle is depressed the valve will be shut, and when the weight acts it will be open. A very similar operation will readily be traced to the valve K, acted upon by the second handle *y*. The lower spindle *z* has a different action on the valve O, which is opened by the rod 14, when the handle is allowed to fall down and shut when it is held up.

The upper spindle has no detent to detain it, but the rod 5 has an equivalent effect. This is jointed to the middle axle, which has its rod and weight *o* suspended from it. In the upper end of rod 5 is a loop in which works a pin, at the end of lever 6, projecting from the upper axis towards the cylinder, whereby, while the middle axis is detained by its catch and detent *t*, keeping the exhausting valve K shut, the valve F will be shut also; but when the catch 1 *t* is discharged, and its weight has opened the exhausting valve, the looped rod 5 will no longer support the lever 6 of the upper axis, and its weight descending will immediately open the steam valve F. It is to be observed, however, that the valve F is not necessarily open when K is open, as the upper one may be shut by depressing the handle *x* without acting at all upon the valve *h*, the slit in the rod 5 allowing this action, which is an essential condition when the engine acts by expansion.

From the injection valve *l* a long wire ascends; this is attached to a strap 9, which winds upon the middle axle, whereby, when the middle handle flies up by its weight, it winds up the strap, and opens the injection valve at the same time with the exhausting valve.

This injection valve closes and opens the orifice at the end of a short curved pipe proceeding from the condenser, which pipe has a cock in it, between the valve and condenser, to cut off and regulate the supply of injection when the cock is open.

It must be acknowledged there is considerable complication in this arrangement; it has been, however, found to be effective; but it is rather given here to show the progress made within a short period, and will serve to put in a stronger light some of the methods now generally adopted. Our object being not so much to give information to those engaged in constructions of this kind, as to point out to the general reader the successive steps which have brought, it is presumed, nearly to perfection, one of the noblest efforts of human ingenuity.

(195.) *Steam pipes and valves in double acting engines.* Steam pipes and valves in double acting engines.
—It has been stated that different masters vary considerably in their methods of working the valves. In fig. 4, we have given a section of the steam ways and valves employed by Messrs. Fenton and Murray; the cylinder itself is not shown, but it will be understood to be supplied by steam through the passages whose sections are shown black at the top and bottom of the figure. C is the steam pipe proceeding from the boiler, and furnished

Manufac-
tures.

with what is called a throttle valve at *a*, to regulate the supply of steam to the engine. This is acted upon by the motion of the lever *b*, and connecting rod *c*, which communicates the action of the governor *g* to the valve *a*; the governor itself receiving its rotation by means of a band passing over a pulley on the crank shaft to a similar pulley on the axle of the governor; *ee* are two levers passing through a slit in the middle of the spindle and turn upon an axle at *f*. The upper part of the spindle is furnished with a socket *h*, which is connected to the lever by rods *ii*; this socket ascends when the centrifugal force raises the governor balls; and, on the contrary, when the motion is slow, and the balls descend, the socket *h* also descends and lever *l* moves with it. *c* is a rod connecting the levers *l* and *b*, which by their joint action communicate the motion of the governor to the throttle valve *a*; so that when the steam engine is at rest the balls *jj* will also be resting against the arms *kk*, the upper end of the levers *ee* will be brought nearer to each other, and the rod *c* being raised, the throttle valve will be turned in a horizontal direction, thus allowing a large portion of steam to pass through the pipe *C*; but after so much has passed as is required, and the engine is put in motion, the balls fly open, the socket *h* and connecting rod *c* ascend, and the valve is brought into an oblique position, shutting or contracting the orifice as the speed increases, which thereby contracts the supply, and checks the speed, so that being once properly regulated, the speed is continued nearly uniform. This action, which it was proper to describe, has no reference to the valves employed for working the engine, as described in the preceding article. These may, however, now be readily explained. The proper supply of steam being admitted to pass through the pipe *C*, it passes through the pipe *a* to either top or bottom of the cylinder, *viz.* to the top of the cylinder, when the valve at *n* is open, and that at *o* shut, or to the bottom, when the latter is open, and the former shut. *E* is the eduction pipe, passing down to the condenser, this pipe being opened alternately to the top and bottom of the cylinder, by means of the valves *p, q*. The valves *n, o* have each a cylindrical tube or spindle passing through the stuffing boxes *r* and *s*. The upper end of each of these has a stuffing, the upper one at *t*, the other at *u*, for the rods of the valves *p, q*, which open to the eduction pipe as above stated, so that either the steam or eduction valves may be opened without permitting the steam to escape.

Fig. 5.

Fig. 5 is a front view of the two sliding rods which give motion to the valves *n, o, p, q*: these rods are kept in a vertical direction by the pieces *z z*, and the guide *l*; the lower end of the rods have friction rollers *3, 3*, which are acted upon by two eccentric pieces *4, 4*, on the horizontal shaft *Z*, which derives its motion from the shaft *Y*, placed at right angles to, and communicating by means of bevelled wheels with, the crank shaft of the engine. Four arms, *9, 10, 11, 12*, are fixed to the rods *vv* and *ww*, for the purpose of moving the valves, and a lever or handle, *13*, turning on a pin screwed on the pipe *E*, is used to open and shut the steam valves when the engine is first set to work, as will be hereafter described. At present, it will be seen that, when the steam valve *n* is open, the eduction valve *q* is also open, the vacuum is then forming below the piston, and the pressure of the steam being applied above this descends. These two valves being now closed, and the steam valve *o* and eduction valve *p* open, the top of the

VOL. VII.

cylinder is open to the condenser, and the bottom to the steam, whereby it ascends with a force equal to that with which it descended, except only the weight of the piston this being in one case additive, and in the other subtractive. The reader will at once perceive the great simplicity of this arrangement in the double, as compared with that of the single acting engine, as above described.

The parts of the figure marked *18, 19, &c., 22, 23, &c.*, are gauges for ascertaining the state of the cylinder and condenser, and are described in a subsequent article.

(196.) *Sliding valves for a double acting engine.*—Here *F* (fig. 6) is the induction pipe, and *D* the eduction pipe, leading to the condenser by means of the passage *G*; *a, b, c, d* is the slide containing a passage *E* through it, and a spindle or rod *O*, by which it is elevated or depressed; the whole slide, as appears from the figure, being less than the length of the cylinder. There are two faces or slide valves at *a* and *c*, which are perfectly smooth and level, and work against equally level faces *e, f*, attached to the side of the cylinder. Between *a* and *c* is a space left or cut away in the slide, so that the steam entering the sliding case at *S*, encompasses it all round except where it is parted at *g* and *h*; the slider being, as shown in the figure, in its highest position. The steam entering at *S*, enters the steam cylinder at the top by the passage or pipe *F*, at which time also the bottom of the cylinder is open to the condenser. The piston, therefore, is now descending, and at a certain portion of its descent, the face *a* closes the aperture *F*, before the face *c* has closed that at *D*; the top of the cylinder is, therefore, shut off from the steam, while the bottom is still open to the condenser. From this time to the bottom of the stroke the steam is acting expansively. The slide having, however, now descended to its lowest position, the aperture *D* is open to the steam entering at *S*, while the slide being now wholly below the passage *F*, that passage is opened to the condenser through the passage *E*, and the piston ascends, by precisely a similar force to that by which it descended, the steam acting expansively during that part of the stroke when the aperture at *D* is shut by the slide *c*.

This is an extremely simple process, and by the whole slider being surrounded with steam, the objection made sometimes to sliding valves, *viz.* the friction to which they are exposed by the unequal pressure on their two sides, is in a great measure avoided; but there was still a great defect irremediable in the packed slide, from the inequality of the packing, which causes an abrasion to be constantly, although slowly, going on, which destroys the faces both of the slider and of the surface on which it slides. We have seen a valve of this kind, which after a few years' wear, had become completely furrowed and worn round, as well as the sliding surface on which it slid; a defect, however, which has been remedied by Mr. Hague, to whom we have several times referred. The motion of this valve is effected by a method very similar to that last described, that is, by eccentrics and levers.

A great variety of methods, besides those above explained, and numerous valves, slides, and cocks have been invented, which would require great space to describe; those above given will, however, furnish the reader with a tolerable idea of the process of supplying and discharging the cylinder of its steam. For more on the subject the reader may consult the Treatises on the Steam Engine by Farey and Tredgold.

tures.

Pistons.

(197.) *Pistons*.—The general reader finds no difficulty in conceiving the nature of the piston; he has only to imagine a truly cylindrical plug, fitting very exactly the bore of the cylinder, but the practical engineer knows the difficulty of putting this idea into practice; it is by no means an easy matter to fit the piston so close as to render the cylinder steam tight, and yet such as to produce little friction between the piston and side of the cylinder. This was one of Watt's first difficulties; the pistons before his time having been kept close by water floating on the upper surface. After many experiments on the nature of different packings, and different unguents for destroying the friction, he finally determined that hemp or tow answered best for the purpose, when lubricated with tallow. According to the best practice of the present day, after all the improvements in boring, &c., the friction is generally estimated in hemp packed pistons at 288 pounds per foot on the contact surface of the piston. With this drawback on the power of the engine it is natural to suppose that great exertions would be made, and great ingenuity called into action to reduce this retarding effect as much as possible, still preserving sufficient contact to secure the steam from escaping.

Hemp
packed
piston.

(198.) *Hemp packed piston*.—This is differently constructed, but a very common form is shown in plate xii. fig. 3, within the cylinder. The bottom of the piston is first fitted as accurately to the cylinder as possible, leaving it at full liberty to rise and fall through the whole length; the part of the cylinder immediately above this is from one to two inches, according to the size of the engine, less all round than the cylinder, to leave a circular or annular space, into which unspun long hemp, or soft prepared rope, is wound as evenly and compactly as possible, to form the packing. This being done, a plate or cover is put over the top, having a projecting ring to fit over the lower part to complete the upper side of the space for packing, being compressed upon it by means of several screws seen in the figure. Both the upper and lower part of the space round the piston to contain the packing is a little curved, that the pressure produced by the screws on the packing may force it against the inside surface of the cylinder into as close contact as possible.

After some time the packing wears so as to go too free, and to suffer the steam to escape; in this case the top of the cylinder must be removed and the screws tightened, which again presses the hemp towards the sides, and restores the proper degree of contact; and this is repeated till no useful effect can any longer be produced in this way. When this happens the piston must be repacked. The piston rod is generally attached to the bottom part of the piston, by means of a conical end, which enters into a similar formed hole in the piston, which it exactly fits, and a screw nut or wedge between the bottom and top is inserted which effectually secures it.

Barton's
metallic
piston.

(199.) *Metallic expanding piston*.—There are a variety of pistons of this description, the first projector of them was Mr. Cartwright. They have, however, been improved upon by subsequent makers, and one by Mr. Barton, which is represented as originally projected by the inventor in plate xii. fig. 7, and in section within the cylinder fig. 6. The bottom plate of the piston is cast iron, and with it is cast the six arms with their projecting circular heads, in which are holes for screwing on the top of the piston, also of cast iron; these arms being formed merely for the sake of lightening the piston, which if the whole were solid would be very heavy.

The bottom and top plates are accurately turned, so as to fit the cylinder very nearly, and the upper side of the lower plate, and the under side of the upper plate are made very smooth by turning and grinding, and round the outside of the projecting radii is placed an iron hoop, also very truly turned; this hoop preserves the top and bottom of the piston, at a perfectly uniform distance all round. Now the space between the top and bottom plates is thus filled. A ring of gun metal (it was first proposed to use iron) the full size of the piston, and exceeding the thickness of the space between the plates, is cut into four segments, denoted by *e, e, e, e*, of the form shown in the figure, between each two of which are triangular pieces of the same metal. These segments and wedges are nicely ground so as to slide very truly between the top and bottom plates above described, which, as already stated, are also ground with very great care. Behind the triangular wedges are placed properly tempered steel spiral springs, which acting against the hoop above described, and the base of the wedges, force these outwards, and cause the segments to expand, the points of the wedges also advancing to fill the little space between them; by this means the cylinder, when very true, is beautifully filled by the piston, and after a little wearing works with a smoothness and freedom scarcely to be obtained in any other way; the cylinder and piston each acquiring the most perfect and delicate polish.

Machinery.

Lately Mr. Barton has discontinued using the spiral springs which were liable to derangement, and has supplied their place by one strong steel spring like a hoop, the ends slightly overlapping; this, by expanding, presses upon all the bases of the wedges, and thus performs the same office as the spiral springs and in a more simple and effectual manner. The breadth of this hoop is of course equal to the depth of the wedges and segments.

It may be remarked, that to save weight the segments and wedges are not solid metal; their section being as shown in the side figure. The piston is perforated with a conical hole to receive a similar formed solid head at the bottom of the piston rod, which may be secured thereon by any of the usual methods.

It should have been observed, in describing the original form, that the segments were in two thicknesses, as shown in the section, and were made to break joint with each other; only two springs are therefore seen, the lower part showing only the empty cavity of the segment. The spring is attempted to be so adjusted as to bring on a pressure of about four pounds per square inch between the cylinder and piston; this, according to the experiments we have recorded on friction, would not make the latter more than two-thirds of a pound per square inch, or 96 pounds per square foot, whereas the packed piston is estimated at 288 pounds. Of this calculated effect, however, there may be some doubt.

A great variety of other pistons have been projected and partially employed; and the reader who wishes to examine their construction, may consult those Works written exclusively on the steam engine; as, for example, the Treatises by Tredgold and Farey, in which are found many other very ingenious contrivances to secure contact, and at the same time to reduce the friction as much as possible.

(200.) *Of the cylinder and condenser gauges*.—In order to ascertain the state of the engine at any time, two barometer gauges are employed, one showing the elasticity

Manufac-
tures.
Description
of the baro-
meter
gauges.

of the steam in the boiler or in the cylinder, and the other the rarefaction of the vapour in the condenser. The cylinder gauge is exactly similar to that attached to the boiler already described, but is represented in fig. 4 as attached to the cylinder by 18, 19, 20, the part of the figure marked by these numbers being a glass or iron tube, as before explained, having a quantity of mercury inserted; this mercury, when the steam in the cylinder is just equal to that of the atmosphere, is equally pressed in both legs, and will therefore rise to the same height in each; when the steam in the cylinder has greater elasticity than the atmosphere, it will rise highest in the leg 18, and when the elasticity is less it will fall in this leg and rise in the other, so that under any circumstances, the power of the steam in the cylinder, or at least in the steam case leading to it, is very readily ascertained: it is sometimes rather less than at the boiler. The connection between the gauge and steam pipes may be cut off at pleasure, by means of the stop cock 19.

The condenser gauge acts a little differently, at least it requires a different form of tube; (see the part of the figure marked 21, 22, 23;) this consists of a bent iron tube 21, the lower end of which is open to the condenser. The mercury is poured into the tube at the open end 23, and the stop cock 22 being opened, the mercurial column at 23 will be depressed, while that on the opposite side will be raised in a proportionate degree. This effect is produced by the vacuum formed in the condenser. If the condenser and air pump are in good order, the mercury will descend about fourteen or fifteen inches, and rise in the other the same quantity, making a difference of thirty inches. This, however, would indicate a perfect vacuum. Generally, if this gauge show twenty-six or twenty-eight inches, the state of the condenser is very good. We have seen that the water in the condenser cannot have generally less than 100° temperature, (Art. 144.) and the vapour of water at this degree is equal to about two inches of mercury, so that it would be useless to aim at greater perfection.

Parallel
motion.

(201.) *Parallel motion.*—In the atmospheric engine, in which the piston was only effective during the descending stroke, the attachment of the piston to the arched head of the beam by a chain was made to answer the purpose of a parallel motion, the ascending motion having been produced by a counterweight. This was afterwards changed for a rack on the piston rod, and corresponding teeth in the arched head, which would thus perform the double stroke. These methods, however, in both cases, were at length superseded by Mr. Watt, by what he terms in his patent a *parallel motion*, and which, notwithstanding some change in its arrangement and variations in the proportion of its parts, has scarcely experienced any improvement.

First me-
thod.
Pl. x.
Fig. 6.

First method.—This is represented in pl. x. fig. 6, where ABH is the half beam, EP the piston rod or pump rod, which is required to move vertically, or nearly so, by the vibratory motion of the beam AB about its centre A. To effect this a rod or link BD is suspended from the point B, where it turns upon a movable joint; to the other end D of this link, another longer bar or link, called a bridle link, DC, is attached, also by a movable joint, its other end turning on a fixed point C. Let the parts be so arranged that the beam AB and the link CD are parallel when the beam is horizontal, at which time the connecting link BD may be conceived vertical, or nearly so. Then a point E may always be found in BD, depending upon the ratio of

the two radii CD and AB, such that, as the beam vibrates about its centre A, that point E shall ascend and descend vertically, or so nearly so as to answer every practical case.

When $CD = AB$, which is commonly the practical case, $BE = ED$, and to the point E the end of the piston rod is connected.

Some authors have bestowed a long mathematical investigation to determine the ratio of BE to ED, that of CD to AB being given, or conversely the ratio of CD to AB, that of BE to ED being known; but the proportion in either case is better found by construction.

When the proportion between AB and CD is given to find the point E, Mr. Tredgold gives the following rule: Let $AB : CD :: m : n$; then from the number n subtract half the square root of four times its square, minus 1 for a first number; also from the number m subtract half the square root of four times its square, minus 1 for a second number; then divide the first number by the first added to the second, and the quotient multiplied by BD the length of the link or bar, will give the distance of the point E from B; that is,

$$BE = \frac{BD \{ n - \sqrt{(n^2 - .25)} \}}{\{ m - \sqrt{(m^2 - .25)} \} + \{ n - \sqrt{(n^2 - .25)} \}}$$

It will readily be seen, that the motion thus produced, although nearly, is not strictly parallel, and therefore all that can be obtained is an approximation; but by fixing the proportions so that the point E may be in the same vertical in three positions, viz. when the beam is horizontal, and when it is nearly at the top and bottom of the stroke, the error out of these points will be very inconsiderable.

(202.) *Second method.*—Here again let AB, fig. 7, be the half beam, and to B and a point C in it towards the centre let two equal hanging links BD, CE be suspended, movable about B and C, and let their ends DE be also connected by a link $DE = BC$, and movable at those points; and again, let the angle E be connected by a bar or bridle lever EG, movable on the fixed centre G and at the angle E. Then the length of EG being taken such that D may fall as much short of the end of the beam when the latter is horizontal, as it falls beyond it at the top or bottom of its stroke, it is clear the point D will, by the motion of the beam, be made to ascend and descend nearly vertically, consequently the piston rod DP being connected with the parallelogram at the point D, this also will ascend and descend vertically as required. The proportion of the lever in this motion admits of great variation; the simplest case is when the radius AC is exactly half AB. Considerable latitude is, however, allowed to the workmen in the lengths of the links BD, CE, without sensibly deranging the parallel motion of the point D, and piston rod attached to it. With the proportions above stated, the centre G will fall upon the same line as the piston, which is often inconvenient, for as there are two parallelograms, one on each side of the beam, the centre of the lever EG cannot be made on one common axis. Eleven different proportions for these levers are given in the following Table, taken by Mr. Farey from actual measure from some of the best engines in and near the metropolis.

Machinery.

Manufactures.

TABLE of Proportional Radii for parallel Motion of the Second Class from actual Measure.

Number.	Length of stroke.	Length of half beam.	Coupling rod D E.	Links C E, B D.	Bridle Lever C E.
	Inches.	Inches.	Inches.	Inches.	Inches.
1	96	147	69	42	78
2	72	120	50	28	96
3	72	110	55	31½	55
4	48	60	41	20	60
5	48	84	38	19½	60
6	48	84	36	20	54
7	48	72	41	18	25
8	45.6	76	40	28	36
9	36	60	37	12	15½
10	24	37	16	9	26
11	23	36	16	12	26

The two great links of the parallel motion are each composed of a strap or loop of iron bent so as to form a double link, in the upper bend of which are two sockets for the pivots at the end of the beam, and at the lower end are two others for the pivots which project on each side the piston rod socket. The brasses of this joint are held in by wedges, put through the two links at the lower end, which, on being driven inwards, tighten the fittings to any degree required.

Other methods of producing parallel motion have been proposed by different constructors, some of which, applicable to other purposes as well as the steam engine, have been described in Art. 77, *et seq.*: Maudsley's mode of effecting this operation is by means of guides in an upright frame.

Description of a single acting engine.

Pl. xiii.

(203.) *Description of Watt's single acting engine.*—This engine was erected at the Chelsea water-works by Boulton and Watt, and has been referred to and described to illustrate the early principles employed by Watt in closing and opening the steam valves, the operation and proportions of the condenser, air pump, and other parts. Here F, pl. xiii. is the steam pipe connecting the boiler and cylinder, the former being enclosed in a case of brickwork, and the latter securely screwed down to the floor of the engine room by the bolts *nn*; its upper end is covered by a lid, through which the piston rod *a* slides in an air-tight box, called a stuffing box. The beam C A moves on its axis or gudgeon at B; and the bearings in which the gudgeons work are sustained by the floor and wall E.

The pump rod *p*, carrying a counterweight, is suspended at the end A of the beam; and both it and the piston rod *a* are connected by a parallel motion apparatus to the working beam C A.

The condensing cistern is at M, and contains the air pump N, the condenser, and hot well *g*; a continued supply of cold water is procured by the action of the cold water pump *y*, and the excess is carried off by a waste pipe to the well *q*; the whole of the external part of the apparatus being kept by that means at the lowest temperature possible.

The upper steam valve is at F, and the lower at *s*, and the exhaustion valve at O. These valves are moved by the plug tree R, which is furnished with tappets to give motion to the levers acting on the valves F, O.

The pump to raise water from the hot well *g* to supply the boiler is marked 20, and the water is conveyed by a pipe to the small cistern 14, on the top of the feed pipe, which is provided with a valve, and acted on by a lever connected by a wire passing down through a

stuffing box to a stone float (see Art. 186.) in the boiler, which by its descent opens the valve, and allows the admission of an additional supply of water when it is required. In order to prevent concussion, two blocks, 13, 13, are fixed across the upper side of the beam, and extend on each side so as to strike on four wooden springs on the floor which supports the beam.

Having as above described the several parts of the engine, let us now endeavour to illustrate its action. Conceive the fire lighted beneath the boilers; all the valves are kept shut by pressing down the two upper handles, *x* and *y*, and lifting up the lower one, their respective catches detaining them in those positions until the steam is sufficiently heated, and the engine is ready to work. In the quiescent position of the engine, when it is at rest, the counterweight always draws the piston fully at the top of its cylinder, as in the figure; the air pump bucket will also be at the top of its barrel.

In order to prepare for setting the engine to work, all the three valves must be opened at once. This is done by relieving the spindles from their several catches, when the weights immediately open the valves. The steam enters through the valve F into the top of the cylinder, and by the pipe *r* through the lower steam valve O, into the bottom of the cylinder, also through the exhausting valve K, into the condenser L, driving before it some air, which passes out at the snifting valve, not seen in the figure. At first, the coldness of the parts condenses all the steam which enters; and it is not until all the iron with which the steam comes in contact, is heated to the temperature of boiling water, that the steam ceases to flow from the boiler in a stream, and be condensed as it arrives at the cylinder and condenser; but after this the steam acquires the same force in the cylinder and pipes that it has in the boiler; it then occupies every cavity of the engine, and, in a little while, displaces all the air in the cylinder, condenser, and pipes, which passes out, and is discharged at the snifting valve. (See pl. xii. fig. 3.) This valve is always covered with water in a small cistern, attached to the side of the large one, to ensure its tightness. Through this valve the air is discharged by the steam, not at every stroke, as in Newcomen's engine, but only at first setting the engine to work, and this operation is called the *blowing through*. It is well known when the cylinder and other vessels are properly heated, and the air discharged, by a very smart crackling noise at the valve, like a violent decrepitation of salt in the fire, which noise is occasioned by the water in the small cistern producing a sudden and rapid condensation of the issuing steam when the air is all gone.

It being known by this sign that all parts of the engine are cleared of air, all the three valves are to be shut, by pressing and holding down the two upper handles *x* and *y*, and lifting up the lower handle *z*, in which situation its catch, 2, will retain it. This cuts off the further supply of steam from the boiler, and also intercepts the passage of the steam from the cylinder to the condenser; and as the cold surface of the condenser still continues to condense a considerable portion of steam, there will soon be none left, and a vacuum will be formed in the condenser, while the cylinder, both above and below the piston, is full of steam. The vacuum in the condenser will soon become perfect from the external cold alone, though more slowly than when an injection is made.

In this state the engine is prepared for starting at a

Machinery

Manufac-
tures.

moment's notice by the engine man letting the two upper handles *x* and *y* rise up by their respective weights; this opens the upper steam valve, and the exhausting and injection valves; the former admits the steam into the top of the cylinder, to press upon the piston, while the latter allows the steam already in the lower part of the cylinder to flow into the vacuous condenser; and at the same instant that he opens the injection cock, the valve is lifted, as also the exhausting valve; this admits a jet of cold water into the condenser, and condenses the steam as fast as it arrives from the cylinder, so that in an instant all the steam in the lower part of the cylinder will be drawn off and condensed. The pressure of the steam on the piston being now unbalanced by any thing beneath it, it descends and draws up the pump buckets and columns of water in the pumps, with a velocity proportioned to the pressure of the steam and the diameter of the piston compared with the height of the column of water in the pumps and the diameter of the bucket; but the piston having descended about one-third of its stroke, a chock or tappet of the plug frame *R* meets the upper handle *x*, and pressing it down, shuts off the steam from the boiler. That part of the handle on which the chock acts becomes perpendicular when the valve is shut, the handle being bent for that purpose; and the chock can, therefore, descend further, and slide against the perpendicular part of the handle, which is straight, without producing any further depression of the handle, at the same time that it keeps it down to the same point, so as to hold the valve shut. The piston, therefore, continues its descent by the further expansion of the steam at first let into the cylinder; but having arrived at the bottom of its stroke, a chock on the opposite side of the plug beam seizes the handle *y*, and presses it down, which pushes a rod 4, until it shuts the exhausting valve *K*, and also shuts the injection valve by the trap and rod 9. When the catch 1 (see pl. xii. fig. 3—*a*) of the handle *y* presses on the upper hook *t* of the detent *t v*, it relieves the catch 2 of the lower axle *z*, and then the weight *n* causes the handle *z* to fall, and pulling the rod 14, opens the lower steam valve *O*. Let us now consider the position of the engine. The middle handle *y* will be held down by its catch 1 holding in the upper hook *t* of the detent, so as to keep the exhausting valve *k* shut, and the upper steam valve *F* is also kept shut, by the same means which kept it shut during the latter two-thirds of the descent of the piston.

Under these circumstances the piston is at liberty to rise by the action of the counterweight *S*, because the opening of the lower steam valve *O* has established a free communication between the top and bottom of the cylinder, and the steam in the top of the cylinder can flow through the pipe *r*, and enter the bottom of the cylinder as fast as the piston rises by the action of the counterweight.

When the piston has returned to within one-third of the top of the cylinder, the chock of the plug frame quits the upper handle; but this handle cannot yet be thrown up by its weight to open the upper valve, because the rod 5, from the lever of the middle axis, bears up the short lever 6, of the upper axis, and thus the motion continues till the piston arrives very nearly at the top of the cylinder: a chock on the plug frame then seizes the lower handle *z*, and, lifting it up, shuts the lower steam valve; and the catch 2 of the lower axis passing the lower hook *v* of the detent, moves it on its

centre, so as to release the catch 1 of the middle axis from the upper hook *t* of the detent. This being the case, the weight of the middle axis causes its handle *y* to fly up, and by the rod 4 it opens the exhausting valve, and, by drawing the trap and rod 9, opens also the injection valve, at the same time the upper axis, losing the support of the rod 5, which kept it up, its weight carries up the upper handle, and by pulling the rod 2 it opens the upper steam valve *F*.

The steam from the boiler is now admitted to press upon the upper surface of the piston, while the steam from the lower part of the cylinder beneath the piston rushes into the condenser, where, being met by the cold injection, it is condensed, and makes a vacuum in the lower part of the cylinder, which brings down the piston to make another stroke.

At one-third of the descent the plug frame, as before, presses and holds down the upper handle, to keep the upper steam valve shut; and when the piston has arrived at the bottom, the plug frame presses down the middle handle *y*, to shut the injection and the exhausting valves; and in catching this discharges the lower axis, and the weight thereof opens the lower steam valve. The piston then rises by the counterweight, and when at the top of its stroke, the plug frame lifts the lower handle *z*, and shuts the lower steam valve, and in catching discharges the two other handles, which open the upper steam valve, the exhausting valve, and the injection valve, and this produces the descent of the piston, as before.

If the air has been fully discharged from all parts of the engine by blowing through, the action of the air pump does not begin until the injection water and the air which are extricated from the water in the boiling have accumulated in some quantity in the condenser; then at every descent of the bucket *d* of the air pump, it dips into the water contained in the bottom of the barrel *N*, and the water passes through the valves in the bucket; these valves shut when the bucket is drawn up, lifting all that water which is above them up to the top of the barrel, and there it is forced out through the hanging valve *g* into the hot well *g*. The drawing up of the bucket at the same time makes a vacuum in the pump barrel beneath it; and if this vacuum is more perfect than that in the condenser, which it will be if the condenser contains either air or steam, it will press by its elasticity upon the surface of the water in the lower part of the condenser, and force it through the hanging valve at *m*, into the lower part of the barrel *N* of the air pump; and when all the water is gone from the condenser, the air or elastic vapour which is in the condenser will follow and enter into the pump until the space of the barrel beneath the bucket is filled equally with the condenser.

This takes place while the pump bucket is at the top of the barrel; and on the descent of the bucket a space beneath it is diminished until it compresses this rarefied vapour so much, that its elasticity will be sufficient to close the hanging valve *m*, and to lift the valves in the bucket *d*, and pass through them into the space of the barrel above the bucket; and when the bucket has descended to the very lowest, the water contained in the bottom of the barrel, not being able to escape through *m*, must pass up through the valves, and rest upon the bucket *d*; when the bucket ascends, it carries before it this water and air, and as it rises, the space of the barrel above the bucket diminishes,

Machinery.

Manufac-
tures.

and the rare vapour or air in it condenses by being pressed into less space, until at last it becomes equally dense with the atmospheric air, and then the water, following it, drives it through the valve *g* into the open air.

The ascent of the bucket *d* left a vacuum beneath it, as before, and this drew a portion of the air or vapour from the condenser into it, ready to be extracted by the next stroke. As soon as the bucket begins to return, the discharge valve *g* shuts, and prevents the atmospheric air from entering into the pump. By this we see that if the vapour in the condenser is so rare that the whole contents of the barrel of the pump will only make a few cubic inches, when reduced, to become equal to the pressure of the atmosphere, this small quantity will be effectually evacuated through the discharge valve *g*, because the water resting upon the bucket follows the air, and will chase every particle of it from the top of the pump, and then follow itself.

The air pump of Mr. Watt's engine requires to be of large dimensions, and the condenser is generally of the same size, by which means the rarefaction of any elastic vapour contained in the condenser will be equal to half at every stroke; that is, the air pump will extract half the quantity of the elastic vapour every time; because, supposing the vacuous space which the bucket of the pump leaves beneath it when it is drawn up to be equal to the capacity of the condenser, then the vapour in the condenser must expand itself to fill a double space, by which one half of it will enter into the pump, and be drawn out by the succeeding stroke, while the other half will remain in the condenser.

The cylinder of this engine is four feet diameter, and eight feet stroke, and the air pump two feet diameter and four feet stroke; thus their areas respectively are as one to four, and their capacities as one to eight. But it must not be considered that this large pump, full of air, is to be drawn out of the condenser at every stroke; for, as we have stated before, the vapour with which it is filled reduces itself to a small quantity before it comes to the density of the atmospheric air. At first we should be led to conclude that the pump affects the power of the engine as a deduction of as much power as the pressure of the air upon the surface of its bucket; but if we consider its construction, having a valve at *g* to keep off the pressure of the atmosphere, it is certain its bucket can have little weight upon the engine, until the bucket is near the highest limits of the stroke; and taking the sum of the resistance from the commencement of the stroke to its termination, it will be found to be very little in comparison with the power of the cylinder.

An air pump of one-eighth the capacity of the cylinder is sufficient to keep the condenser empty, when it is a single engine. If a smaller air pump were employed, it must be in action to lift out the air and water, for a greater portion of its stroke.

In fact, whatever the size of the air pump may be, it will occasion little more resistance to the engine than from the friction of its bucket, except during the time that it has actually opened the valve *g*, to discharge the air or water which it contains; before that period, the resistance is only that of compressing the vapour, an operation which begins at nothing, but increases by an ascending proportion reverse to that of the decrease of the pressure of the steam, when acting in the cylinder by expansion, as we have before explained.

In Mr. Watt's early engines the air pump and con-

densing cistern were placed at the outer end of the Machinery beam; and there are some reasons to prefer that mode of construction where the building will admit of it. In this case the pump bucket being drawn up by the descent of the piston, the engine requires a less counter weight than in the form just described, in which the air pump must be wholly worked by counterweight. Also, it is during the descent of the piston that the action of the air pump is most necessary; and it is possible that an engine, having the pump worked by the outer end of the beam, may make a better vacuum than when it is worked by the inner end, because there may be some, though a very slight, impulse given to the remaining air of the last stroke, by the rush of steam into the condenser at the instant the steam piston begins to descend, and the air pump to rise; for no sooner is the exhausting valve opened, than the steam rushes towards the condenser, and giving a momentary tendency to a plenum therein, may give a push to the air through the hanging valve, between the pump and the condenser; and hence it is reasonable to conclude, that more air will enter the pump by this means, than if it were left to its own expansion.

It is necessary that the parts appropriated to the condensation of steam should be kept as cold as possible, and those intended for the operation or passage of the steam as hot as possible; hence the air or discharging pump and condenser are placed in the cistern of cold water, which is kept constantly full by the cold water pump, and a little running away into the well to carry off the excess of heat; and if the injection valve is placed low in this cistern, it will take the water in the coldest state. The injection valve and cock are best seen in pl. xii. fig. 3.

As the condensing apparatus is immersed in water, to be kept cold, so the cylinder should, if possible, be immersed in steam, to be kept hot; for which purpose, Mr. Watt, from the first, used a casing or jacket round the cylinder, and also at the top and bottom: this was attended with very beneficial effects, although it enlarged the steam surface, and exposed the external jacket to a more rapid condensation than would have taken place from the surface of the cylinder itself. But to have the vacuum as perfect as possible, it is necessary that the cylinder be kept up to such a temperature as to prevent the least condensation of the steam upon the internal surface, either above or below the piston; because, if the sides of the cylinder were to be wet, as in the common atmospherical engine, the vacuum would be vitiated, as there would be occasioned by this wetness a moisture gradually forming to steam, which the outside casing prevents when filled with steam from the boiler, and the heat which escapes from the surface of the jacket does not injure the operation of the engine; but if it were possible to cover this outward case again with any sort of substance which would entirely prevent the transmission of the heat from the casing, it would supersede the use of the jacket altogether, and would apply with more advantage to the cylinder itself; but we do not know of any substance which will not admit this transmission more or less. Some of Messrs. Watt and Boulton's best engines we have seen surrounded by a case of polished copper, we believe outside of the jacket.

In small engines it is common to place the cylinder within the boiler, and it must then be kept fully as hot as the steam which enters it; but this is not practicable in a large engine, nor is it advisable in any case, because

the frequent repairs which the boiler requires must derange all parts of the engine.

When the jacket is used, a small copper pipe is conducted from the steam pipe to keep it full. As the jacket of a large cylinder must be exposed to be heated or cooled less than the metal cylinder to which it is attached, the unequal expansion might break the joints; to avoid this, the jacket is made in two halves put together in the middle of the length, without any other attachment than that of entering into each other for three or four inches, with a cup which is packed with hemp and tallow. The steam pipe has a similar joint which unites it to the box of the exhausting valve K, and will admit of drawing out a little without permitting the steam to escape.

(204.) *Double acting engine.*—Having in the preceding explanation of the single acting engine, entered into a minute description of the action of the air pump, condenser, and several other parts which are common also to the double acting engine, it will not be necessary again to recur to these particular points, but briefly to explain the general construction and principle of the engine. We select for this description an engine of Murray and Wood of twenty horse power; but it may be considered as a general description, the principal difference between one and another consisting in the manner of opening and shutting the valves, and some other minutiae. In this engine the working the valves is effected by eccentrics placed below the valve rods; in others by an eccentric working a lever connected with these rods and balanced by a large counterweight: in some cases the slides for opening and closing the valves is packed at the back, in others, the slide is kept up to the face by the mere pressure of the steam against the opening leading to the vacuum. This latter is the arrangement of Mr. Hague of Ratcliffe, and the action or pressure is said to be found much more uniform than with the packed piston. It is however impossible to attempt a description of all the different principles which have been introduced. We give the following, therefore, as a general illustration of the action of the double engine. Here (plate xiv.) is the representation of the engine. B is the cylinder inclosed in its steam jacket; C the pipe conducting the steam from the boiler to the steam case or valve tube D; E the eduction pipe leading to the condenser F; G is the air pump; H the cold water cistern; I the cold water pump; and K the hot water pump; the action of each of which are sufficiently shown in the drawing; L the piston rod connected with the parallel motion; S is the connecting rod between the beam Q and crank T; this gives rotation to the toothed wheel U, which, working in another wheel on the axle V, gives again rotation to the shaft V and fly wheel W; and other wheels on this shaft, or on the crank shaft, give motion to the Machinery intended to be worked by it. Sometimes the fly wheel is on the crank shaft, and by straps this fly wheel is made to work other fly wheels at some distance. This is the case in Woolwich Dock-yard, in the engine employed to work the large hammer and rolling mill. X Y Z are three bevelled wheels, the first of which is attached to the crank shaft, and, by means of the intermediate wheel and shaft Y, gives motion to the third, which by two eccentric rollers moves the valves. This is better seen in plate xii. fig. 4, which is an enlarged representation of this part, seen endwise, and the particular action of which has been already described in Art. 195.

The governor is worked by a band *b b* passing over a pulley on the crank shaft, and another on the vertical axis of the governor itself, which latter is also shown enlarged in the figure referred to above. To put the engine in action the fly wheel W must be turned till the crank T is in a horizontal direction, when the piston will be in the middle of the cylinder B, and the eccentric wheel be on the upper side of the shaft Z. The bar *w w* will also be raised together with the valves *v* and *p*, and the handle B being turned a passage will be opened for the steam to blow from the pipe C, and thus expel the atmospheric air, which previously filled the different parts of the engine. When this is effected, and the temperature of the engine is raised, the lever B must be turned to its original situation; the bar *v v*, together with its valves, will descend, and the steam will be shut off from the upper part of the cylinder, while at the same time the passage will be stopped between the under side of the piston and the condenser. The injection cock must now be opened, which will admit a small jet of cold water into the condenser, and a partial vacuum will be formed above the piston, while the steam is entering beneath with a pressure equal to that shown by the gauge above the atmosphere. The piston rod being thus made to descend in the cylinder, the opposite end of the beam will be depressed, and the rod S and crank T will also descend, and a rotary motion will be produced. The fly wheel also will have acquired a sufficient degree of momentum to carry the crank past the perpendicular, and the piston will have arrived at the top of the cylinder. The situation of the valves being reversed by the action of the eccentrics, a continuous motion is thus produced.

(205.) *High pressure engine.*—This engine was one amongst the earliest steam engines, at least in imagination, having been suggested by Leupold in 1720; it was also one of the principles of working which formed a part of Watt's patent, and was attempted by others, but was not brought into actual practice till 1802, by Trevithick. This is the more extraordinary as its principle of action is so much more simple than the condensing engine. In the latter a vacuum is produced, or partly produced, on one side the piston, and the steam acting on the other side, the piston is urged forward by the difference between the two; now in the high pressure engine the piston being opened to the atmosphere instead of to the condenser, is pressed on one side by the atmosphere, and on the other by the pressure of the steam. This, therefore, only requires the steam to be raised to a higher degree of elasticity, which being effected, all the apparatus of condenser, air pump, cold water pump, &c. are immediately dispensed with, and the engine assumes a very simple character. Trevithick's engine, however, was not of this simple kind, its entire figure and construction having been such as to fit it for the purpose of locomotion, which was the principal object of the inventor, and to him we owe the first demonstration that such object might be effected by the power of steam. Having, however, this specific object in view, we beg to refer the reader for a further description to the Chapter on the application of steam to locomotive engines.

Many high pressure engines resemble in all their exterior form the usual double acting vacuum engine, but as the beam is not so essential in an engine working by high pressure steam, as in the low pressure engine, this is very frequently dispensed with.

Manufac-
tures.

Pl. xv.
Fig. 1 and 2,

Vibrating
engine.

Howard's
vapour
engine.

An engine of the latter kind is represented in plate xv. where fig. 1 is a front elevation, and fig. 2 a side elevation. The cylinder CC is supported upon cast-iron framing AA firmly bolted down to the beams BB. To its upper end are attached the cast-iron sides DDD, which serve to guide the piston rod of the cylinder in a truly vertical direction, by supporting two wrought-iron rods *aa*, which pass through an enlarged part of the cross head EE, which works the crank FF on the main shaft of the engine. The steam is conveyed by the pipe SS to the box CC containing a slide valve, which admits the steam to the top and bottom of the cylinder through flat pipes cast in its thickness. Motion is given to the slide by a heart-shaped crank on the main shaft, shown by the dotted lines at *d*, fig. 1, which works inside a rectangular piece of wrought iron, forming part of the vertical spindle *ff*, and conveys to it by its rotations a reciprocating motion, which by the horizontal lever *gg* is communicated to the slide rod. *kk* is the throttle valve, which, as in the common engines, is regulated by a governor C, put in motion by a system of bevelled wheels from the main shaft.

(206.) *Vibrating engine*.—This is an exceedingly simple construction, and, in cases where the power is not great, is very convenient. It may be worked either by high or low pressure steam, or by means of a vacuum, as described in a subsequent article. It was the original invention of Mr. Witty, but it has been more largely constructed by Mr. Hague, engineer, Ratcliffe, than by any other person. Some difference is found in the construction of this engine, but principally in the method of admitting the steam; and lately, Mr. J. Maudsley of Newington has taken out a patent for a method of admitting the steam very nearly in the same way as in the usual engine. The more common method is to suspend the cylinder on two strong, hollow, cylindrical trunnions, at its centre of gravity in proper bearings, and supported by two sides of a cast-iron frame; on each side of one of the supports two pipes, or openings are carried through the side of the frame, in either case opening at top into the bearing on which the engine swings; one of these pipes opens downwards into the atmosphere in the high pressure engine, or into the condenser or vacuum in the other cases, while another pipe is connected with the boiler. Two openings are formed in the axle on which the cylinder is supported, and which communicate with the top and bottom of the cylinder, whereby, when the engine is set to work, these openings or valves are alternately connected with the induction and eduction pipes, as the piston ascends or descends, this being made to work a crank which produces the required rotation. This description will here be sufficient, as an engine of this kind is represented in a figure, and its action more particularly illustrated under "Application of the steam engine to navigation."

(207.) *Howard's steam or vapour engine*.—The variety of forms which have been given to the steam engine within the last thirty years is so great that to attempt any thing like a description of them would require a large volume. Many of the combinations and arrangements are exceedingly ingenious, and possess perhaps some advantages for particular purposes; but few if any have acquired that degree of notoriety to justify us in entering upon a further description of them than we have already done. We are, however, disposed to make an exception in the present case. The object attempted in this engine is to dispense with the boiler, by producing

the steam only at each stroke of the engine. We have seen the engine at work at the King and Queen Iron Works at Rotherhithe, and to every appearance it was performing its duty remarkably well: it was afterwards examined by Mr. Kingston, the engineer in His Majesty's Dock-yard at Woolwich, and on his report one is now allowed by the Admiralty to be put for trial in the Comet steam packet. If it should be found successful on this large scale it will undoubtedly be a most important advantage in steam navigation; the room at present occupied by the boilers being a serious deduction from the space of the vessel. It is a low pressure engine, acting by condensation, and differs in no respect in form from Watt's double acting engine, but it is stated to require only half the fuel of the latter. The following is the inventor's own description. In the vapour engine, a high temperature acts upon such small quantity of liquid as will produce only a low comparative density, so that the rapidity of vaporization is not impeded by a corresponding pressure. This is effected as follows.

The heat from a coke fire is conveyed to the surface on which the vaporization is performed, through the medium of such quantity of mercury as will render the varying intensity of the fire, &c. sufficiently manageable: its temperature being indicated by a thermometer, which, when water is employed, should not be much lower than 400° Fahrenheit, but may be allowed to fluctuate between that and 500°, without perceptibly affecting the power of the engine. The surface exposed to the fire, in the engine of ten horses power now at work, is the bottom of a shallow wrought-iron pan, containing the mercury, and presenting to the fire seven square feet, or three-fourths of a square foot per horse power. It is placed beneath the working cylinder, which is twenty inches diameter. With alcohol a still less surface will suffice. Above the mercury is a very thin covering of iron, so contrived as to present about four times the fire surface, and is throughout in close contact with the mercury beneath. The vaporization is effected by dispersing upon the latter surface, at intervals, (say each stroke of the piston,) through a nozzle adapted to the purpose, the required small quantity of water, alcohol, or other liquid, previously heated to about its boiling point, which is instantly and completely vaporized. The quantity of liquid injected, on which the power of the engine is dependent, is regulated by the movement of a small valve, adjusted either by hand or by a governor. It is not necessarily presumed that any advantage would result by employing mercury, or other fluid medium, in the ordinary boilers or generators.

The fire is supplied by a blowing machine with air, which passes through a regulating valve, and is so admitted to the fuel as to act uniformly on it. A chamber surrounds the working cylinder into which the vapour passes, previously to its entering the latter by the induction valves. The heat from the fuel, that has not been absorbed by the mercury, passes, prior to reaching the flue, through a casing enclosing the chamber, by means of which the vapour within the latter is heated, say to about 400°: at the same time the pressure is in general only twenty or twenty-five pounds per inch, including that of the atmosphere. Thus, instead of the considerable loss of effect from condensation which takes place in the steam engine, an additional expansion is given to the vapour after its formation, to the extent of nearly one half; that is, one volume of steam at 212° become: one and a half at 450°.

Machinery

Manufac-
tures.

Machinery

In order to improve the process and save fuel, the vapour is worked expansively, for which it is well adapted; being cut off from the cylinder at about a fourth of the stroke, giving, for instance, an average pressure throughout the stroke of twelve pounds per inch, when the pressure for the fourth part is twenty pounds per inch. The quantity of coke consumed by the present engine, worked with water, is forty-five pounds per hour, or four and a half pounds per horse power; and it is expected that it may be further reduced.

The condensation is performed by *injection* in the following manner:—The condenser is a copper vessel, placed in a cistern constantly supplied with cold water, and receives the vapour or steam from the cylinder by an eduction pipe as usual: two pumps, worked by the engine, are connected with the bottom of the condenser, and a copper pipe proceeds from them, which, after many coils in the cistern, so as to expose a sufficient surface to the cold water, enters the condenser at the lower part, being furnished at its termination therein with a loaded valve. Such quantity of liquid is introduced into the condenser as will entirely fill the pipe and pumps, and enable the latter to act effectively. The pumps continually withdraw the warm liquid from the bottom of the condenser and pass it along the pipe, by which means the heat is abstracted from it, when, being injected through the valve amidst the vapour, (admitted into the condenser from the cylinder,) it instantly reduces it to the liquid state. No air being introduced, (as in the steam engine with the injection water,) a very small air pump is sufficient, being merely employed to exhaust it at starting, and what may enter by casual leakage. The condensation is fully as rapid and complete as in the best steam engine. A small pump conveys the liquid from the condenser to the valve before described, attached to the vaporizing apparatus. This process of condensation is equally applicable to the steam engine, with the important advantage of allowing the same water to be continually returned to the boiler.

(208.) *Method of conducting steam power to a distance from the engine.*—It is of course desirable to have the steam engine erected on the spot where its power is to be applied; but it happens frequently, that power for occasional purposes may be wanted at some distance from the spot on which the engine stands. Sometimes in mines, a certain power in the galleries to bring carriages up inclined planes, or even to stamp ores on some level where there is an adit of water, is very desirable, although it might be dangerous or inconvenient to have the steam engine in these places. In the occasional working of cranes and other Machines on the tops of buildings, on wharfs, and in a variety of other cases, it may be attended with great convenience to be able to apply the power of a steam engine situated at a distance in another part of the establishment; a principle of working which has been carried to a considerable extent by Mr. Hague, a very ingenious engineer, of Ratcliffe, to whom we have already frequently referred.

This is effected by having an air pump worked by the engine applied to a close vessel, so as to produce a vacuum or a rarefaction to a certain amount, and to have a pipe leading from this vessel to the point where the power is wanted; at this place a cylinder like that of a steam engine may be employed, the power which gives motion to its piston being the alternate opening of its top and bottom to the pressure of the atmosphere, while the other side of the piston is opened, by means

of the communicating pipe, with the vessel in which the rarefaction is produced; by this means a pressure equal to the difference between that of the atmosphere and that in the rarefied vessel, is the motive power, and may be employed in the same manner as that of the steam in the high pressure or low pressure engine. According to this principle of working, it is found best to have the rarefaction carried to about half the atmospheric pressure; and, consequently, the capacity of the air pump cylinder must be equal, or exceed double that of the working cylinder. This working cylinder is generally made to act on the vibrating principle, described Art. 206; and in the few cases the writer of this article has seen, the performance is very satisfactory, little or no power appearing to be lost by this mode of transmission: an object which it would perhaps be impossible to accomplish in any other way; besides, the great inconvenience which must attend any mode of connection by ropes or otherwise, would, in most cases, prevent a proprietor of works from availing himself of the spare power of a distant engine, whereas, in the way above described, no inconvenience of any kind is experienced. Mr. Hague has thus in one case carried the spare power of an engine to a distance of two miles, and in several instances the power of an engine at the pit's mouth of a mine has been conducted into one or more galleries. This mode of communicating power is also now generally employed in the processes of coining, as will be seen under that article.

(209.) *On the actual power of the steam engine.*—In several of the preceding articles it has been necessary to refer to the power of the steam engine, the consumption of fuel, &c., but we have generally made merely an estimate, and have not hitherto entered minutely into this question. It has been stated, that the most common unit of comparison is the horse power, and each horse power is estimated by the number of pounds raised in a minute to the height of one foot; Watt assuming this number to be 33,000 pounds. This of course includes time as an element; but another method of estimation, also proposed by Watt, was, to estimate the power, or, as it is called, the efficiency of an engine by the number of pounds which may be raised one foot by the consumption of a bushel of coals. Here, however, time is not an element, and is not therefore apparently so proper a form of comparison as the former; we shall, however, examine the action according to both forms.

When Messrs. Boulton and Watt had brought their engine to perfection, they charged their profits in proportion to the saving of fuel effected by it, as compared with a common engine of the same power, and burning the same coals; one-third of these savings having been paid them annually, or the whole amount, adequately adjusted for prompt payment, paid in one sum. This comparison, however, was not to be made on the recent engines of Smeaton's construction, he having already effected considerable saving, as has been shown in our Historical Chapter. Smeaton had undoubtedly reduced the consumption of coals about a half or a third; and Watt had again reduced the consumption to about one half of that used in Mr. Smeaton's best form; so that, upon the whole, it may be said that Watt saved in the comparisons by which he was guided, about three-fourths of the fuel originally consumed, and one-third of this saving he enjoyed the advantage of during his exclusive right granted by the original patent and its Parliamentary extension.

Boulton and
Watt's first
engines.

Manufac-
tures.

The power which was assigned to his engine in the earliest constructed ones, was, that they should raise 500,000 pounds of water one foot high, by the consumption of one hundred-weight, or 112 pounds of coals, which is equivalent to raising twenty-four millions and a half pounds one foot high by the consumption of one bushel of coals. This, however, seems to have been an over-rated statement; or, at least, it belonged only to the most perfectly constructed engine, and when in its best state for working; for, by an experiment of Mr. Smeaton, who was desirous to promote by all means the introduction of the condensing engine, he obtained a result of only nineteen millions. This experiment was made on an engine on the Birmingham canal, for returning into the reservoir the water let down by the passage of boats through the locks. The working cylinder was 20 inches, and the pump also 20 inches, lifting 27 feet, at the rate of 11 strokes per minute, each stroke being 5 feet 9 inches.

Here $20^2 \times .7854 = 314$ square inches area, or $\frac{314}{144}$

square feet raised one foot high per minute;

$$\frac{314}{144} \times 5\frac{3}{4} \times 11 = 138 \text{ feet}$$

raised 27 feet per minute.

Hence $138 \times 27 \times 60 \times 62\frac{1}{2}$ pounds = 13,961,805 pounds raised one foot high per hour.

The coals (which were the Wednesbury) consumed in an hour, were 65 pounds; and hence

$$65 : 88 :: 13,961,805 : 18,902,136 \text{ pounds}$$

raised a foot high, which, calling it nineteen millions, is considerably below the estimate above stated. And yet this was probably a favourable case; for it appeared in 1811, that the general medium of the Cornwall engines, which were principally of the construction of Boulton and Watt, did not exceed an effect of more than thirteen millions and a half raised one foot by a bushel of coals. Much of this deficiency was, however, no doubt due to the inattention of the engineer; for about that time comparisons being made between the different engines, and their working powers regularly registered and reported, the engineers felt themselves as it were responsible for the performance of those under their immediate charge; and the consequence has been, that from a medium of thirteen millions and a half, they have been gradually increasing in power, till, in one instance, an engine was made to perform for several successive days the amount of one hundred and three million pounds raised a foot high: it did not, however, continue working at this rate, but settled down steadily to eighty millions, which it still continues to perform. This is quite on the maximum side at present, but almost daily improvements in the economy of working the engines is going on in Cornwall, so that it is difficult to foresee to what length it may ultimately be carried. The gradual annual improvement will be seen by the following short Table, stating the number of engines in several successive years, and their average duty actually performed.

	No. of Engines.	Average Duty.
In 1811	—	13.5 millions.
1823	55	26.9
1824	57	28.
1825	62	28.97
1826	63	28.36
1827	62	31.9
1828	64	34.85

Cornwall
single act-
ing engines.

Further particulars relative to these engines will be given under the *Application of Steam Engine to Mining*. It will be sufficient here only to remark, that they are mostly single acting, and being principally employed in pumping or raising ores, they may be perhaps worked more economically than those used to produce rotation, and to drive Machinery, whose diameters, velocities, pressure per square inch, and other minutiae, are more restricted. Generally in the smaller engine of the latter kind, the capacities and length of stroke are so arranged that the surplus pressure (after deducting the friction and resistance of air, pump, piston, &c.) is such, that this pressure on the whole piston amounts to a hundred and fifty pounds multiplied by the number of horse power, and the speed two hundred and twenty feet per minute; but in the larger engines, the pressure is a hundred and sixty-five, multiplied by the nominal horse power, and the speed about two hundred feet per minute. Some variation, however, in these respects, is made by different makers; but the following Table shows the general proportions of what are esteemed the best land engines. In steam vessel engines the strokes are generally shorter, but the pressure, diameter, and speed are the same, the diminished length of stroke being compensated for by a greater number being made in a given time.

The surplus pressure on the piston cannot be correctly ascertained in any way, except by knowing the actual duty the engine is performing; but the real pressure is easily determined, being equal to the difference of the pressure on the steam and vacuum side of the piston. The pressure on the steam side is, of course, equal to that shown by the steam gauge plus the atmosphere, and that on the condenser side is equal to the difference between the vacuum gauge and the barometer.

Thus, if the steam gauge show 6 inches,

the pressure on the steam side is $6 + 30 = 36$ inches

And if the condenser gauge show 28, the

pressure is $30 - 28 = 2$ inches

Difference 34 inches

Or 17 pounds per inch;

and about one half of this, or rather more, is generally supposed to be absorbed by the air pump and friction of the engine, leaving a surplus pressure of from seven pounds and a half to eight pounds and a half effective; the former in the smaller, and the latter in the larger engines.

The reader will see that as, in the above calculation, the atmosphere enters equally on both sides, and the difference is then taken, the result is the same as adding together the amount shown by the two gauges; that is, the actual pressure in the above case is equal to $6 + 28 = 34$ inches, or seventeen pounds per square inch. And this is the general language of engineers, who, as we said above, afterwards consider the half of this to be the effective pressure; but as the smaller engines have proportionally more friction than the larger, the former are commonly considered to average about seven pounds and a half, and the latter eight pounds and a half. Some, however, consider only half the pressure shown by the condenser gauge to be absorbed, as we have before stated, but we believe few engines arrive at this degree of perfection.

Machinery.

TABLE, showing the Dimensions, Velocities, Pressures, and Consumption of Coals per Horse Power per Hour, Machinery for Engines of different nominal Powers, both Single and Double acting.

Nominal Horse Power		Dimensions of Pistons.			Load on the Piston.		Velocity of the Piston, Length of Stroke, &c.				Weight raised 1 foot high in a minute.		Consumption of Coals per Hour.			
Double acting.	Single acting.	Diameter in inches.	Area in square inches.	Number of square inches for each Horse power.	Pressure per square inch.	Load on Piston.	Length of Stroke.	Number of Strokes per minute.	Velocity Double acting.	Velocity Single acting.	Cubic feet of Water.	Pounds Avoirdupois.	Double acting.		Single acting.	
													Pounds per Horse power.	Total.	Pounds for each Horse power.	Total.

Manufac-
tures.

Application of the Steam Engine to Mining.

(210.) We propose under this head, not merely to confine our description to the working of the steam engine for the purpose of raising water or minerals, the stamping of ores, &c., but to take also a general view of the history of mining, both of metals and coals, to which mineral productions Great Britain is so highly indebted for her elevated rank amongst nations; and which sources of wealth and power must ever have remained buried far below her surface, but for the invention and subsequent improvements of the steam engine.

To the difficulty of working the deeper mines, there can be no doubt we owe, if not the invention of the steam engine, at least that spirit of encouragement which brought it to perfection; and the engine has in return furnished the means of working mines which, but for its aid, must ever have remained unexplored. It will, therefore, it is presumed, not be considered out of place, while we are pointing out the extraordinary assistance which our mining districts have derived from this engine, if we take a concise view of the art of mining, and the produce derived from it prior to this invention, as the reader will thereby be the better able to appreciate the importance of its application in these operations.

History of
mining for
tin and
copper.

(211.) *History of mining for tin and copper.*—Of all the mineral productions of England, there seems no doubt that tin was the first known; this metal, according to most historians, forming an article of commerce in very ancient times with the Phœnicians, long before the invasion of this Country by the Romans. Tin works were certainly carried on before the use of iron was known, and probably before it was known to possess metallic properties. Many tools of oak, obviously used in mining, are occasionally found in old works, which tradition amongst the miners ascribes to the Saxons and Danes, but which were, in all probability, the rude instruments of the ancient Britons. Mining at this time must have been of a very simple character. Without the means of raising either ores or water, except by manual labour, and without iron to separate the blocks in which it might be discovered, it is pretty obvious, that at this time but little penetration could be effected below the surface; consequently, those metals were first worked which presented themselves nearest to the surface, and of this kind is tin. It is indeed probable, that nearly all the tin procured in former Ages was by means of stream works, in bottoms or low grounds, where fragments of the ore, washed from the *lodes* in the neighbouring hills, subsided, and were separated from the earth in a granular form by washing. This, of course, was obtained without any subterraneous work; and in such situations as these, probably, metals were first discovered, mixed merely with the upper soil, or lodging in the clefts of rocks: thus gold is found in Africa, in America, and other Countries. The tracing the ore into the earth itself, would almost follow as a necessary result, as soon as the surface failed of yielding a sufficient supply; and at this point the art of mining commenced, and the difficulties of the operation began to be experienced. At what time this took place, it is of course impossible to say, or, confining our remarks only to this Country, at what part, but most likely, from all records, in Cornwall and Devon. The difficulty which must have attended the keeping a mine, sunk to some depth, free from water by manual labour only, could not but prevent men, before the application of Machinery, from proceeding far

below the surface of the earth; and yet there are examples of old works which have been carried to a great depth; but these, though now old, were probably, indeed certainly, long subsequent to the early periods above referred to; and after iron, and the means of applying the powers of horses to mills or windlasses, had become known.

Many rocks are so hard as to yield with difficulty to manual effort; at least in such a degree as to render the operation profitable. As far as the process could be conducted, hammers and wedges were most probably employed for splitting the rocks, as they are still in ground that will yield to them, the pick or instrument for cleaving the ground being furnished with a head for driving the wedges, called by the Cornish miners *gads*. These instruments are sometimes found in old works, and their figure, it is said, bears strong testimony of their antiquity. Wedges of dry wood were also very ingeniously made use of, by driving them into the clefts and then wetting them, so as to cause them to swell and force the ground asunder. Fire also was employed to produce this effect; but it was only after the discovery of gunpowder that the miner was possessed of the power of separating into fragments the hardest blocks. This agent so far exceeded any other before made use of for such purpose, that its discovery and application to works of this kind form a grand epoch in the history of mining. This, it appears, took place in Hungary or Germany, about the year 1620, and was first introduced into England at the copper mine at Ecton, in Staffordshire, by German miners, brought over by Prince Rupert; but it was not in use in Somersetshire till 1684, after which, probably, the Cornish miners became acquainted with it. This discovery of gunpowder greatly facilitated mining operations, and hydraulic machines were constructed in situations where they could be fed by streams for raising water and the ores; and water wheels are still had recourse to where they can be worked conveniently with the same object, as well as for stamping and other processes; but it was the discovery of the steam engine which crowned all previous Arts, and gave a dominion to the miner he could never without it have dared to expect.

To recur again to the earlier period of mining in England, it appears that after the Romans left this Country, and it fell under the sway of the Normans, that the working of the mines was a good deal neglected; at any rate they seem to have been unprofitable, and to have been principally in the hands of the Jews, but began again to revive in the reign of Richard II. Edward I., however, having banished this unfortunate race, mining was again neglected, till Edmund, the eldest son of this Monarch, made some important alterations in the regulations of the tin works of Cornwall by a Charter, which was confirmed by Edward in the latter part of his reign. Indeed, it is from this time that the peculiar laws and privileges relating to the Stannaries are chiefly to be dated. Mining infringed in some instances on property, and caused disputes, besides requiring indulgences not general; and thus causes arose not cognizable by the common law. In this way a peculiar code, springing from custom, took its rise; and though this in some measure existed before, yet it was not till this period that it was confirmed by Royal Charter, and enforced by subsequent Acts of Parliament. It was by this Charter that the bounding land to the purpose of tanners working on it, the duties to the Earl of Cornwall, and the coinage of tin, or stamping with the Earl's

Machinery

Manufac-
tures.

seal, were first established. Before the reign of Edward I. tanners worked in the Earl's land only, paying him a fifteenth part of what they got, and they were not at all permitted to dig in sanctuary ground, churches, mills, houses, gardens, and so on; and, if in working under, they chanced to subvert any house, or to damage a high way, they were obliged to make it good. When it became an object to search throughout any place or person's lands, a Court also to determine cases relating to the tin works became necessary; and this adjudging under authority of, and according to the code of laws before mentioned, was first established by Edward I., and is called the Stannary Court.

In Cornwall and Devon two different systems of Stannary laws now exist: those in Cornwall have been from time to time amended and corrected; but in Devon, where mining has for a long while slumbered, the laws continue in their original crude state.

The Duke of Cornwall had Royal jurisdiction; and when the Duchy came into the hands of the Crown, which happened in the reign of Edward III., he made his eldest son, the Black Prince, the Duke, and appointed the Dukedom, with the revenue arising from it, to the sons and heirs apparent of the Crown, though no son of the King can be Duke of Cornwall but the first-born, even though heir-apparent.

The Stannary laws were explained and confirmed with some alterations at different times, till Arthur, eldest son of Henry VII., made certain constitutions relating to the Stannaries, which the tanners refused to observe; the King, after Prince Arthur's death, seized the Charter as forfeited, but granted a new one with fresh privileges, appointing all new laws relating to the tanners to be made by a Parliament of their own body; and upon this footing the Stannaries remain.

Great powers have been at times assumed by this jurisdiction: it has even taken upon it the trial for felony in the case of a tanner; in general, however, the cases where its authority interferes, are in disputes concerning tin-works, or between tanners; it provides a supply of water to a tin-work, giving a power to conduct it through any lands for that purpose.

Copper, of which so much is now sent from this part of the country, was not an object attended to till a comparatively late date by the Cornish miners; even in tin mines, which as they deepened produced copper, as is often the case, and where they needed to raise this ore, it was thrown by as of no value, going by the name of *poder*. Those who lived in later and more enlightened times reaped the profits left to them by the ignorance of their forefathers; and this proves of what consequence it is to determine, if possible, the

value of all the substances passing under the miner's observation.

Copper, however, was probably worked at a remote period in Wales, at Parys mountain, which, indeed, is supposed to derive its name from the Celtic word *praas*, brass or precious metal; and this would offer a proof of its having been worked by the ancient Britons. It was not, however, attended to, or at least not well understood in England till the reign of Queen Elizabeth, who paid great attention to the mines of the Kingdom, and, by granting great privileges to Daniel Haughsetter, Christopher Schutz, and other Germans whom she invited into England, commenced and established the highly valuable and important business of finding and purifying this useful metal. To these foreigners, too, is owing the flourishing state of our brass manufactories. In this reign Parys mine was granted to patentees, but was not worked, at least to any advantage, for a century and a half.

The copper mines of Cornwall are now works of great magnitude, many of them are sunk to amazing depths, some exceeding two hundred and forty fathoms, and are kept working at a vast expense. The quantity of materials constantly used forms an extensive commerce, which, together with the mines themselves, give employment to a very extended population.

We cannot enter into a minute statement of the several particulars of the different mines in this County, and much less of the general mines of England, but the continued and progressive annual product of the several mines, according to the best authentic returns, will occupy but small space, and be interesting to the reader, as it will be also to see the immense amount of steam power employed in the mines of Cornwall only. We have not the means of making a similar statement relative to the other mines of England, but assuming it proportional to their product, we shall find that the steam power employed in Great Britain for mining only, exclusive of iron and coal mines, amounts to the labour of one hundred thousand horses, or to that of five hundred thousand men; it is also interesting to observe how greatly the power of the engines individually have been progressively improving within the last twenty years. The reader will see by referring to the Chapter on the steam engine, that what is in the following Table denoted average duty, is the number of pounds raised a foot high by the consumption of one bushel of coals - and it will be seen (Art. 209 and 215.) that this average duty of the best engine in 1813 was only 26,460,000, with a mean average of 19,456,000, whereas in 1828 it amounted to 76,763,000, with a mean average of 34,850,000, and has more recently exceeded 80,000,000 in the best engines.

The produce of the first nine months of the year 1828 was 21,749 blocks, or 3,642 tons.

(215.) *Account of the Quantity of Lead raised from the Mines of Great Britain.*

As no regular accounts can be obtained of the produce of this metal from mines dispersed in so many districts, the quantity can only be estimated, and the following are the results of a careful inquiry amongst those who are best acquainted with the subject. The produce of each district in which mines are worked is stated upon a comparison of various authorities, and exhibits a considerable increase when compared with a similar estimate made about five years since, when the whole appeared to be about 36,000 tons.

	Tons of Pig Lead.
1828. Mines of Weardale, Alstone Moor, Teasdale, Derwent, &c., in Cumberland, Durham, and Northumberland	22,000

Steam
power
employed.

(216.) We have before alluded to the extraordinary power of the steam engines employed in these operations, and the improvements which have recently been introduced into the principles of working them, particularly in Cornwall, where great attention and specific reports are made of their performance. Many of these engines are single acting engines, some double acting, and several are worked upon Woolf's principle; but the greatest duty is obtained from the largest of the single acting engines worked expansively. Some of these have cylinders of ninety inches diameter, and for a few days an engine on this scale worked at the rate of duty expressed by 103 millions, but afterwards declined without any sensible cause to 80 millions, at which it continues; that is, the consumption of one bushel of coals in the former instance produced a power equivalent to lifting the enormous weight of 103 millions of pounds a foot high, and settled steadily to lifting 80 millions, whereas a very few years back 24 millions were considered a maximum, and 15 very satisfactory duty. The improvement in this respect is indeed very astonishing, as appears from the following Table of the account of coals consumed at the Dolcoath mine at different depths of level. This Table is given by Mr. Taylor in his *Records of Mining*, as follows.

(218.) The following Table shows the amount of duty performed by the several Cornish engines in the month of February, 1834, for which the writer is much indebted to Mr. Davies Gilbert, who has very obligingly supplied him with it.

Mine.	Engine and the diameter of the cylinder.	Length of the crank.	Length of the stroke, in the cylinder.	Diameter of the fly Wheel.	Number of heads.	Time.	Consumption of coal, in bushels.	Average height which every head lifts, in inches.	Number of times which every head lifts at a stroke.	Number of strokes.	Weight of heads and lifters in pounds.	Pounds lifted one foot high by consuming a bushel of coal	Number of strokes per minute.	Engineers' Names.

Stray-Park	195.53

In reference to the quantity of water drawn by the steam engines from the mines, it should be observed, that some of the engines deliver the water to the adit level, through double columns of pumps; others by Shammal engines, that is, they deliver the water at a level beneath the adit, whence it is drawn by another engine to the adit level. There are other steam engines assisted by hydrostatic engines, in which case the quantity of water cannot be correctly ascertained, and consequently the account is omitted.

T. L.

(221.) *Work performed by the following Steam Engines, in February, 1834.*

Mines.	Engine, and the diameter of the Cylinder.	Load per square inch, on the piston.	Length of the stroke in the cylinder.	No. of lifts.	Depth.	Diameter of the pump.	Time.	Consumption of coal.	Number of Strokes.	Length of the stroke in the pump.	Load in pounds.	Pounds lifted one foot high, by consuming a bushel of coals.	Number of strokes per minute.	Remarks, and Engineers' Names.
		lbs.	Feet.		fms. ft.	Inches.		Bush.		Feet.				
Wheal Unity.	Wood engine, 52 inches, single.	11.5	6.66	1 2 1 2	38 0 35 0 30 3 31 0	9 16 7½ 5	Jan. 31, to Mar. 1.		410290	5.75 5	24624 4094		9.8	Drawing the load in two shafts perpendicularly. Main beam over the cylinder, two bobs and 59 fms. of horizontal rods at the surface, and 55 fms. of horizontal rods under ground. SIMS AND SON.
Ditto.	Western engine, 60 inches, single.	14.25	7.25	4 1 1	72 0 21 5 3 5	16 16¼ 13	ditto	2976	342600	5.75	50818	33638749	8.2	Drawing perpendicularly. Main beam over the cylinder, one balance bob at the surface, and two under ground. SIMS AND SON.
Poldice	Sims's engine, 90 inches, single.	7.6	10	1 5	4 3 111 0	13 17½	ditto	4624	414350	7	69114	43352444	9.9	Drawing perpendicularly, with main beam over the cylinder; one balance bob at the surface, and one ditto under ground. SIMS AND SON.
Wheal Damsel.	Stephens's engine, 50 inches, single.	10.8	9.33	8 1 1	157 0 11 0 5 0	9 6 7	Jan. 31, to Feb. 28	769	157140	7.25	27322	40477241	3.9	Drawing the load perpendicularly 100 fms., and the remainder diagonally. Main beam over the cylinder; one balance bob at the surface. SIMS AND SON.
Wheal Jewell.	39 inches, single.	10	8.5	1 1 1 1 1	32 5 32 3 20 3 11 3 11 0	10 9 7½ 8 6	ditto	564	193990	6	16934	34947092	4.8	Drawing the load in two shafts perpendicularly with main beam over the cylinder, and two bobs and 112 fms. horizontal rods at the surface. SIMS AND SON.

TABLE continued.

Mines.	Engine, and the diameter of the cylinder.	Load per square inch, on the piston.	Length of the stroke, in the cylinder.	No. of lifts.	Depth.	Diameter of the pump.	Time.	Consumption of coal.	Number of strokes.	Length of the stroke in the pump.	Load, in pounds.	Pounds lifted one foot high, by consuming a bushel of coals.	Number of strokes per minute.	Remarks, and Engineers' Names.

Estimate of the aggregate power of the steam engines in mines.

(222.) It is difficult to form a correct estimate of the aggregate power of these engines; the particulars are always referred to the combustion of one bushel of coals as a unit without reference to the time of consumption; but by comparing a few cases, and computing the actual weight raised per minute, it appears that although these engines work very economically, as far as regards consumption of fuel, they are not individually equivalent in horse power to common engines of equal diameter of cylinder. From the comparison of the actual load lifted in a minute with the diameter, they appear to be deficient in power in about the ratio of eleven to fourteen, as compared with usual engines.

By estimating each engine in nominal horse powers according to its diameter by the Table, Art. 209. it appears that the aggregate number of nominal horse powers of the Cornwall engines amount to 4182, but as they are of less power, in the ratio of eleven to fourteen, than common engines of the same diameter, this reduces the horse powers to 3362. This nominal power is, however, eight hours work per day, whereas these engines work all the twenty-four hours, so that they are, in effect, equal to 10,086 nominal horse powers, which, as we have seen, Art. 4. is equal to 15,129 actual horses' labour; and each horse being equal to 5 men, it follows that the work performed by the Cornwall engines is equal to the power of 75,645 men; and assuming the steam power employed in other mines in Great Britain in proportion to their quantity of mineral product, the whole amount of power will be equivalent to 500,000 men.

Since the above was written we have been favoured with the following curious calculation relative to the power of these engines, with reference to the power requisite to raise one of the great Pyramids of Egypt. The comparison was before made by Baron Dupin; but the following, which is by Mr. Davies Gilbert, is founded on more exact data, and extends to other comparisons, strongly

illustrative of the power of the Cornish steam engine: it is an extract from a letter addressed to H. T. de la Beche, Esq. dated Feb. 23, 1834.

"I have not lost any time in answering your queries respecting our engines and the Pyramid; the base of the first Pyramid is said to be a perfect square of 687 feet, and that each face is an equilateral triangle. Its height must then be $687 \times \sqrt{\frac{1}{3}}$ or 485.78 feet. And its cubic content $687^3 \times \frac{1}{3} \sqrt{\frac{1}{3}} = 18,040,000$, or about 18,000,000 of cubic feet. And assuming the specific gravity of the materials at $2\frac{1}{2}$, the weight will be 1,253,000 tons, about 2,807,000,000 of pounds. The space through which the materials of a Pyramid are raised is well-known to be the same as would be gone through by raising the whole to the height of the centre of gravity, which is one quarter part, or $\frac{484.78}{4}$, giving 374,190 millions of duty.

"In the best Cornish engine a bushel of coal produces above 100,000,000 of duty, consequently a ton of coals, or bushel weighing 84 pounds, will do $26\frac{2}{3}$ as much, or 2,666,000,000 of duty; and consequently 127.82 tons of coal would raise the Pyramid. Now the steam engines of Cornwall, and the smelting furnaces in Wales, are said to consume at the least a thousand tons of coal daily in raising and in manufacturing copper; therefore that quantity of coal would be equal to raising 2853 Pyramids in the course of a year.

"To obtain, however, the average of the best engines in constant work about a third must be taken off, leaving then above eighteen hundred Pyramids.

"The mines of Cornwall are stated in the printed Report of the engines for the last month, January 1834, that they are altogether lifting 20,000 gallons a minute, but the heights are not mentioned; but as the deep mines produce by far the largest quantity of water, the mean height may perhaps be taken at 120 fathoms, or

Manufac-
tures.

720 feet. In that case the duty performed each minute will be 20,000 gallons $\times$ 10 pounds $\times$ 720 = 144,000,000, or 144 millions in a minute.

"The New River has been found to flow with the velocity of three feet in a second, through a channel four feet wide, and four feet deep; $4 \times 4 \times 3 = 48$ feet in a second, or 2,880 feet in a minute. Now a cubic foot weighs 62.32 pounds nearly, consequently 179,499 pounds of water flowed by in a minute.

"The whole course of the New River is 42 miles, and the descent 5 inches on a mile; 210 inches = 17.5 feet in the whole. But $179,499 \times 17.5$ give 3,141,000 in a minute.

"But the steam engines of Cornwall, performing an actual duty of 144,000,000 in a minute, are equal to forcing back to its source near Hertford the New River nearly 46 times repeated.

"The 20,000 resisting the engine in a minute = 3209 cubic feet, or 1850 millions of cubic feet raised 720 feet in the year. The solid content of Westminster Hall being little more than 1,000,000 of cubic feet.

Every thing relative to the Pyramid was made three times too great, by squaring the base and multiplying by the height, instead of one-third its height. It is corrected in the preceding calculations.

Two other minerals, iron and coal, not included in the above estimate, remain to be noticed; but as these are frequently found in the same vicinity, and the working of them differs essentially from the mines of copper, tin, and lead, it is proposed before we proceed to enter upon a description of these, to endeavour to explain the processes followed in working the copper mines of England, and particularly those of Cornwall.

Definition
of terms.

Definitions of the Terms and Description of the Processes employed in working Copper and Tin Mines.

(223.) It does not belong to this Essay to enter into a Geological examination of the theories which have been advanced relative to the formation of the veins of metals with which various rocks are interspersed, nor the rules by which the Mineralogist is guided in following or intercepting them. These are more appropriately discussed in our Treatises on GEOLOGY and MINERALOGY. Our business here is only with the mechanical operation of extracting the ore from the rock, and of reducing it to a proper state for being converted into the pure metal. It will be proper, however, before we proceed, to define a few terms peculiar to the mines, and in some cases to the Cornwall mines only.

Pl. xvi.

Lode is a term used to denote any regular vein, whether metallic or not, but more commonly it implies a vein containing metallic ore. In mining districts these lodes are observed to have a prevailing direction, but by no means general. In Cornwall and Devon the prevailing direction of the lodes is East and West.

The underlay of a lode is a term used to denote the direction of its inclination with regard to the horizon, which, in the same districts, is commonly to the North, although some productive lodes are found which dip in a Southern direction.

Veins which intersect or cross the East and West lodes nearly at right angles are called *cross lodes*, or *cross-courses*, but when they differ greatly from this they are called *counters*. These cross veins are seldom productive of copper or tin in much abundance, but lead is sometimes raised from them in great quantities.

The size of lodes, or width, vary from a few inches to several feet, but from two to four feet is considered profitable to work, if fully impregnated with metal. The size, however, is very uncertain in the same lode, varying frequently from several feet to a mere branch, after which it will sometimes open again to its original size, or exceed it. These veins extend through rocks of different characters, without deviating from their line, although they frequently vary in width and productiveness as they pass from one to the other. Thus a vein that is large and productive in soft blue killas, will, by passing into harder, become less in size and poor as to metallic percentage; another may be rich in hard ground and poor in soft, but this is not so frequent as the former case. The deposits of metals are also as uncertain in the lodes as the width of them, the ores being found to occupy only certain parts, and differ considerably in extent, both in length and depth. No lode, we believe, is known to preserve a regular impregnation of metal, although some are much more constant in this respect than others, but generally it is partially distributed, and when found in pretty large quantities, it is called by the miners *bunches* or *shoots*. Although bunches or shoots of ore have no regular form either in horizontal or vertical extent, yet the tendency to a partial direction or dip in a lode may be observed in every such bunch, and they are frequently parallel in the same vein; and where the dip or underlay is to the North, the shoots of ore may frequently be observed to dip to the West in the lode. This rule, however, is liable to great exceptions, as is also the direction of the vein, as well as that of its underlay. In the great Kappisberg mine in Sweden two of the principal veins are in direction nearly at right angles to each other, and their underlay varying also to nearly the same extent.

Lodes continue to indefinite lengths, and to unknown depths; it is very difficult to determine whether the termination of any regular vein has been reached, as instances occur of their having become so small as to be scarcely visible, and yet afterwards on pursuing them they have resumed their usual size; but when a lode has continued small, either in length or breadth, for any considerable distance, it is usually abandoned, so that complete evidence on this point is never ascertained. Lodes are as perfect at the surface of the mountain as in their greatest depths, and may be traced regularly by removing the soil with which the rock is covered. This is constantly done by the miner when he is about to undertake new operations; and this gave rise to certain privileges formerly conferred upon the tin miners of Cornwall, who were permitted to open grounds of other persons in such pursuits. This was called *shoding*. The width, however, of a lode at the surface is no certain sign of its size at any depth; for frequently when broad at the surface they become of little size as we descend; and on the other hand lodes of small width on the surface become of great size at some fathoms down.

Lodes are seldom found to preserve a directly perpendicular line, and even their underlay or inclination from the perpendicular is not uniform throughout. These will vary from one foot to four feet per fathom, and some even have still greater inclination than four to six, but they are seldom considered to offer so promising a prospect as those of less inclination.

When it is intended to sink perpendicular shafts the underlay of the lode must be ascertained, in order to meet them at certain depths, and according to this incli-

Machinery.

Manufac-
tures.

nation the shaft must be commenced at the proper distance at the back of the vein; but sometimes shafts are sunk upon lodes, are not then of course perpendicular, but partake of the inclination of the lode itself; sometimes, also, after proceeding perpendicularly for some distance, the miner will take the direction of the lode, and thus form inclined planes, connecting one level with another: these levels are driven on in the substance of the lode, follow its direction, and are the principal means by which discoveries of ore are made and pursued.

It has been stated that a vein or lode may be traced on the surface of the mountain by removing the soil, or by shoding, and it is thus that many veins have been discovered; or they may be discovered accidentally on the formation of roads, ditches, and such like processes: the latter case, however, is one of pure accident, the former is pursued for the express purpose, some indication having been observed by detached fragments of ore being found, or by springs of water being discovered impregnated with metal.

Another method by which veins are discovered is in running an adit for the discharge of water from some mine already in work, or for any other purpose; but such levels, when they are intended to be made for such purpose, should be carried across the prevailing direction of the lodes, being of course by this means more likely to intersect some unknown vein, than when driven in any accidental direction. There are, however, minute points for observation on the surface, which guide the experienced eye of the miner in these pursuits, which it is impossible to describe, and which indeed, if it were possible, would not properly belong to this article, which only professes to describe the actual practical operations after the lode itself and its direction have been ascertained. We shall therefore now suppose that the position of the vein is known, and confine ourselves merely to a description of the mode of sinking, working the levels, draining and pumping the water, raising the ores, and stamping, and otherwise reducing them to a state fit for smelting.

Operation
of sinking.

Pl. xvi.
Fig. 1.

(224.) *Operation of sinking.*—This is, of course, in the commencement very simple. Two or more men are employed digging, while two others at a common winch and barrel raise the soil. After a certain depth, the labour of raising becomes greater; and then sometimes a sort of capstan is erected, and a greater number of men are employed in the latter operation. This is afterwards changed, as the depth increases, to the employment of a horse mill, working what is called a *whim* or *whimsy*, that is a large hollow kind of drum, on which the rope is wound, which brings up the materials, and which mode is pursued afterwards throughout the working, but the horse mill is ultimately substituted by a water wheel, the steam engine, or other Machine. When the first shaft is run out of the perpendicular, taking the inclination of the lode, then of course the material is brought up on an inclined plane; but generally, whatever may be the direction of the working shaft, a vertical shaft is afterwards sunk to communicate with some of the levels, and through which the ore is raised, and by means of which the mine is kept dry by pumping, if there be no other means of discharging the water by an adit run into the sloping face of the mountain. As the work proceeds, however, the shaft becomes deeper than the adit, and then Machinery, such as has been described, must be had recourse to: when a supply of water can be had to work a water wheel it is preferred for its

cheapness, but generally we may say the steam engine Machinery. is adopted in most English mines. We have, indeed, shown that in Cornwall alone the steam engine power employed is equivalent to 15,000 horses, or to 75,000 men.

(225.) When the shaft is sunk sufficiently deep, and it becomes desirable to pursue the lode horizontally, it is stopped for a time, and a level is pursued on each side of it; and this is usually continued in two opposite directions upon the course of the vein. The ends of these levels being driven to some distance out of the way of the shaft, sinking may commence again and continue till it is thought proper to drive another level, and then a succession of these galleries or drifts are opened under each other, and the vein is thus divided into parallel portions, which are left to be worked for the ore contained in them. These are in Cornwall commonly called *backs*. New openings are made from the surface to these levels, by sinking more shafts at proper distances, and communications from one level to another are sometimes formed by sinking small underground shafts, in which the soil is raised by the common windlass. When a mine has arrived at this state, and a sufficient supply of ore seems probable, proper engines are erected, provided with a requisite power to admit the constant deepening of the mine, by keeping the bottom of the engine shaft dry, so as to be regularly sinking; ventilation is also now to be attended to and put in an effective state, by means of the different shafts and levels, and Machines constructed for the purpose of bringing up the ores and waste to the surface, worked as before stated either by water wheels or steam engines; and when thus provided, the mine is said to be, and is, in fact, in due course of working. These shafts and levels are kept constantly sinking and driving to lead to further discovery, or to open more of the lode for working; and the parts of the vein or lode left between the passages thus made are worked away, where the ore will pay the expense of so doing, by men who contract for this work within certain limits, being paid a proportion of the value when merchantable, which is called tribute, and which varies with the degrees of facility with which the ore can be procured, either from the different states of richness of the lode or the hardness or softness of the rock which must be broken to obtain it. A considerable improvement has taken place in this kind of working of late years, by which it is said half the expense of the labour has been saved; this is by working from the lower level upwards, instead of proceeding from the upper level downwards; in the former case the rubbish being left in the place where it falls, whereas in the latter it has to be removed.

The ore is usually conveyed in wheel barrows through the levels under ground by boys to the nearest shaft, and there raised in buckets or *kibbles* to the surface; these kibbles are received in some cases on a board slipped under them when slightly above the surface, and the ore thence removed to its proper places for undergoing subsequent operations. These latter require various hands, principally women and children. The object being to separate from the ore both the stony and sparry waste, as also the mundic and other useless metallic matter with which it is combined; operations performed by hammers and requiring some skill and practice. The better parts of the ore being thus separated, are reduced to a proper size by passing them between two cylinders of iron of unlevel surfaces, or by flat hammers, but usually now by the former method. The coarser parts

Modes of
working.

Manufac-
tures.
Pl. xvi.
Fig. 4.
Description
of stamping
mill.

require much more labour; they are first reduced by the stamping mill, and then undergo the operation of sifting and washing. A stamping mill is represented in plate xvi. fig. 4; this is worked by a water wheel or steam engine, but in Cornwall very frequently by the latter. The mill consists of a long coffer or strong box, made of the firmest timber, and the ore is conveyed to it by a trough: it is not suffered to fall into the trough at once, but is stopped at the mouth by a cross board, and water is turned upon it, which washes in a proper supply. In this coffer there are several stampers placed between strong timbers, having braces or cross pieces on each side to keep them steady, and to assure their vertical direction; their heads are of iron, weighing from thirty pounds upwards, according to the nature of the work to be performed; and the stampers, to the ends of which these heads are fixed, are about eight feet in length, and about eight inches in breadth, having in-timbers or guides between them, as seen in the figure: two tongues are attached to the back of each, which are caught by wipers fixed on a barrel turned by the engine. These wipers are so placed as to catch the tongues on the stampers, and thus to raise them by two lifts, when they fall with great force on the ore beneath. The frequent and powerful blows thus given soon reduce the large masses into a sort of sand, which is washed out of the trough by the continual current of the water made to pass through the coffer. The powdered ore is then conveyed out of the trough into what is called the *launder*, which is a trench cut in the floor, about eight or ten feet square. This is stopped at the lower end by turf, so that the water is all suffered to pass away, and the powder of the ore stopped. Another method of working these stampers has been lately proposed by Mr. Hague, and is in progress of adoption in the Cornwall engines, by giving momentum to those stampers by means of a vacuum, on the same principle as that employed in coining. We have already, in Art. 208, shown the method by which the power of a steam engine may be made available at any required distance from the engine itself; and in this way that vacuum principle is conducted to cylinders, to the piston of which the stampers are affixed, and so arranged that their bottom part is open to the vacuum, and their upper part to the atmosphere to give the blow, and the contrary to raise them; the efficiency is thereby rendered much greater, and more precision is introduced into their action than in the common method. Moreover, by this means the power of an engine may be carried down to any level of a mine having an adit, and the stamping and washing take place there, instead of being at the pit mouth, or, as frequently is the case, at some considerable distance from it; by this means a great quantity of matter is carried away at the adit, which must otherwise have been brought to the surface, and, consequently, much labour is thus saved, particularly in poor mines.

The management of these surface operations is usually confided to a *dresser* or *grass captain*, who regulates the whole, the expense being borne by the men who raise the ore on tribute, and who take their proportion of the value according to the amount of the sales, and, therefore, pay every previous charge.

The erections on the surface of a mine comprise, besides the steam or water engines, whims, stamping mills, and sheds on the dressing floors, a suitable counting-house for the captains and clerks, pay-offices, &c.;

VOL. VII.

also blacksmiths' and carpenters' shops, timber house, Machinery. and every other attachment which the constant wear and frequent repairs to be made render necessary, which it is difficult and unnecessary to particularize more at length in this place.

(226.) *Pumping*.—We have hitherto spoken of pump- Pumping. ing as a simple process; but it will readily be conceived, in mines of 200 fathoms deep, that much difficulty must attend this operation, which will require some particular description. A pump rod 1200 feet long is not managed with the facility of those which more commonly fall under the observation of the general reader. Some lines of illustration will, therefore, form a necessary part of this article. In plate xvii. fig. 1, 2, we have given a representation of a shaft of a mine, with the ladders for descending and the pumps for raising the water. For this interesting figure we have been indebted to the *Records of Mining* by Mr. Taylor; and from the same Work we have also made an abstract of the explanation.

As water can only be raised about thirty feet by suction, it seems to have been concluded that neither could it be by lifting; and thus it appears the lifting pumps for mines are described by Agricola. At what time this erroneous view of the subject was first corrected does not appear; but Delins, who wrote his Work on mining in 1765, describes what he calls the low pumps and the high pumps; and he reasons on the advantages of the latter as if they were not then generally understood, or in common use. This is not extraordinary, as even at this time it is not uncommon to have it propounded that a lifting pump can only raise water about thirty feet; thus confounding the height to which water can be raised by atmospheric pressure with that to be obtained without other alteration of the Machine than extending the length of the pipe upwards above the piston. By this construction, as the fluid cannot return through the valve of the piston, the column will go on increasing above it at each successive stroke till it reaches the top of the pipe, and will afterwards continue to flow out. This is the simple form of the lifting pump of mines, by which, with one lift and with one piston, water is often raised 150 or 180 feet, equal to five or six times the height due to atmospheric pressure. Delins states the advantage of these high pumps, observing, "that as the depths of the shafts are generally very considerable, and too much for a single pump, a number must be applied, one over the other, so as to raise the water into the adit. Each one discharges its water into a cistern; in this is fixed the suction pipe of the pump immediately above, which lifts the water into another cistern. These columns of pumps are of different heights, and the preference of one certain height over the other is a matter much disputed.

"As to the charge of water, in long pumps as in short ones, there is not the least difference as to the proportion of power required in the Machine to raise it, while the cylinders, or working barrels, are equal; for if, in a depth of thirty fathoms, there are two lifts of pumps of fifteen fathoms each, or six lifts of five fathoms, which are all of the same diameter, the load which the Machine has to overcome is perfectly equal, and, consequently, no difference in this respect exists. It is then a question to be considered, whether from other circumstances the one is preferable to the other. Let us, therefore, compare one of the lifts of pumps of fifteen or sixteen fathoms with three lifts of five fathoms each.

2 E

Manufac-
tures.

The three short lifts will have three working barrels, three pistons or boxes, three valves beneath, and three times as much leather; and in the rods and connections there will be three times as much iron-work as in a long lift.

"It is certain then, that the consumption will be triple, and cause great additional expense, when the working barrels and the boxes are of brass. If, also, the power of the Machine is diminished, by want of water way in the suction pipes or wind bores, this evil, which ought chiefly to be avoided, is, by the greater number, much increased, and in short lifts three times as great as in the long ones.

"It is again very clear, that the piston or box causes a great deal of friction in rising and sinking in the working barrel; and, consequently, with the greater number ought to be estimated as threefold. From all these circumstances, it is reasonable that we should prefer long lifts of pumps to short ones; yet it may be objected to the latter, that the pipes, on account of their own height, and that of the column of water they contain, are subject to leak. This may be true where they are made of wood, and when the length is too much extended; nevertheless, experience shows that those resist pressure perfectly, and do not leak to a height of fifteen or sixteen fathoms, if they are properly bound with iron hoops.

"It has been objected, also, that the friction of the boxes is more considerable on account of the greater load, that it is necessary to have more timber in the shafts to sustain the pumps, and that it is more difficult to draw the boxes to change the leathers; all which are trifling considerations, compared with the real advantages that the long pumps possess over short ones." These observations, made in the earlier stages of the application of this very important apparatus, have been proved to be correct in the further experience of their use. In England, where iron pipes have of late years been substituted for those made of wood, and the leakage in that manner avoided, which Delins was obliged to admit might limit the length of columns of pumps to 15 or 16 fathoms, we have been enabled to extend the lifts with advantage to 30 and even 40 fathoms in height, so that mines which in this Country are commonly drained by pumps to the great depth of 160 or 180 fathoms, have only five or six columns of pumps for the purpose.

Description
of the
pumps.
Pl. xvii.
Fig. 1, 2.

(227.) In our plate xvii. fig. 1 and 2 are intended to represent mine pumps, supposed to be working in a shaft about ninety fathoms below the adit, consisting of three lifts. A is the upper part of the shaft above the adit level; B the adit or level into which the water is pumped, and by which it passes off to some opening or out-fall in the side of the hill; C is the main rod which gives motion to the pistons of the different lifts of pumps either buckets or plungers. This rod vibrates up and down, being impelled either by a steam engine, water wheel, or other appropriate Machine; D, D, D, set-offs on the main rod for connecting the pump rods of the different lifts; E the cistern of the upper column of pumps, which delivers to the adit; the cistern receives its supply of water from F, the *collar launder* of the middle column; G is the cistern of the middle column; H the *collar launder* of the lower, having drawing pump and iron pipes. Generally, in this Country, all the pipes are iron, but in the plate the upper or standing pipes are represented as formed of wood, to indicate how this

material may be employed in Countries or situations where the expense of iron pipes might be thought objectionable. It will readily be seen by the figure, that the lower lift only is worked by what is termed the lifting pump, the other two being forcing pumps, worked by solid plungers. Suppose this pump in action, and the main rod ascending, by this motion vacuums are formed in the three working pipes K, L', L'', and the water rushes to supply these vacuums, first from the water in the well filling the pipe K, and from the cisterns G and E into the plunger pipes L', L''. The water in the pipe K is then retained by means of a common clack box at L, and in L', L'', by valves placed at N' and N''. Now on the downward stroke, the valve in the bucket K of the lifting pump, opening upwards, admits this bucket to descend, while the plungers K', K'' force the water through the H pieces which unite the plunger pipe with the standing pipe through the valves at O' and O'', the latter forcing water up to the adit B, where it is discharged, and the former into the cistern F, to supply the vacuum in L' formed by the next ascent of the plunger K''. No water is raised by the descent of the bucket rod in K; but this takes place, of course, during the ascending stroke, so that in the ascending stroke the water is raised in the lower lift, and during the descending stroke in the two upper lifts. By this arrangement, the down stroke of the engine, which corresponds with the up stroke of the rod, is employed in raising the bottom lift of water, and the whole weight of the pump rod, plungers, &c.; and it is by the weight of the latter only that the plungers raise the water in the two upper lifts.

By this means the counterweight, which would be necessary if all the pumps were on the common lifting principle, is avoided; and as this counterweight, to balance such a length of rod and plungers, must be enormous, great convenience and economy is thus attained; besides that the plungers, having no friction or wear except at the stuffing box through which they work, and which packing is readily tightened by the proper collars provided for the purpose, no stoppages of operation are thus occasioned beyond what two or three men can readily correct; whereas in the common buckets the wear from gritty matter, and from the corrosion of the water, is such as to render repairs continually necessary.

It will be seen in the figure, that in order to facilitate any repairs or correction in the valves, square plates are screwed on the face of the valve boxes, which may be removed, the repairs made, and the plates replaced in the least possible time. The operation of the valves above referred to, will be readily comprehended by the figures given in the plate; it is only necessary to state, that an iron bow is attached to the lower box for the convenience of drawing the clack, and that rods are placed below for guiding it again into its place when the repairs are completed.

The further processes to which the different ores are submitted to reduce them to pure metals, is given under the head SMELTING.

(221.) *Iron and coal mines.*—We have hitherto confined our attention to mines of copper, and such metallic ores as occur in veins; we are now to describe the method of conducting mining operations in those cases in which the mineral is deposited in strata or beds, as is generally the case with coal and iron, but the methods of working are so nearly the same in these two cases that a

Machinery.

Coal and
iron mines.

Manufac-
tures.

description of the one will apply equally to the other. The immense quantity of coal requisite for reducing iron ore to the metallic state is such, that if these two minerals were not found in the same vicinity, at least in this Country, it would be impossible to produce the metallic iron at such a price as to be marketable. It is fortunate, therefore, that this contiguity has place in so many districts in England. In Wales, generally, both the iron and the coal lie in mountains which are entered in their face; and the operation of mining consists in simply excavating a tunnel, or driving a head, as it is technically called, into the side of the hill, the bottom of which serves as a drain to the water of the mine, while the mineral, whether ironstone, or coal, is brought out in small waggons called trams, on roads of iron of the old construction, and which, from the name of the carriage, are called tram roads. The steam engine, therefore, in these cases, is wholly dispensed with for the purposes of the mine. These over-ground workings, however, are not general; even in Wales and in many parts of England both minerals are raised from great depths. The operations in deep mines being, as above stated, so exactly the same for both coal and iron, it will be sufficient for our purpose to give a description of one; and as the working for coals in the neighbourhood of Newcastle is conducted on the grandest scale, and carried to the greatest depths, it will perhaps be most interesting and instructive to the reader.

History of
iron mines
in England.

(229) We have been enabled in the preceding part of this article to give some slight sketches of the history of the tin and copper mines of England; but the period at which our iron works commenced, seemed to have wholly escaped the records of historians; its history being a complete blank till about the year 1577, and all we learn then is, that iron was made in England at that time, but was dearer than foreign iron. This notice is given by Holinshed; and in 1678, a short Memoir was printed in the *Phil. Trans.* No. 137, by Henry Powle, Esq. descriptive of some iron works in the Forest of Dean, and which it appears had been carrying on for some years before, as it is said "that the country formerly bore very stately oaks which are at this time nearly destroyed by the extension of the iron works."

It is also stated, "that in former times, when their works were few and their vend small, they made use of no other bellows but such as were worked by the strength of men, by reason of which their fires were much less intense than the furnace they now employ." "This is furnished with two huge pair of bellows whose noses meet at a little hole near the bottom; these are compressed together by certain buttons, placed on an axis of a very large wheel, which is turned about by water, in the manner of an overshot wheel; as soon as these buttons are shot off, the bellows are raised again by the counterpoise of weights, by which they are made to play alternately, the one giving its blast while the other is rising."

In another part of the same Paper it is stated, that several attempts had been made to introduce the use of sea-coal in these works instead of charcoal; the former being to be had at an easier rate than the latter; but that the trials had not been attended with success. In 1693, we have another communication to the Royal Society, No. 199, by Mr. John Sturdy, describing some processes followed, and the nature of the ore employed

at iron works in Lancashire. They have in this country, it is said, "several sorts of ironstone and of different natures, for some make cold short iron, such as is brittle when it is cold, another sort makes red short, such as is apt to break when it is hammered at a dark red heat, and is therefore never melted down but in mixture, and so it yields an indifferent good sort of iron." Of late, it is observed, they have made it much better by melting the same metal over again, and by using turf and charcoal, whereas formerly their fuel was only charcoal. "They once tried pit coal but with bad success."

Machinery.

These notices, although they throw no light upon the early history of working iron in England, show the state in which the Art stood at the commencement of the XVIIIth Century; it was at that time, if not in its infancy, in a very imperfect state, and, in all probability, the quantity produced was very small; about fifty years after, the weight of iron manufactured in England amounted to 17,000 tons annually, from which time to the present it has been gradually increasing, till the annual amount, at this time, is nearly 700,000 tons.

Whether any works of this kind had been, in early times, established in Wales does not appear; but these now form a most important portion of the iron works of Great Britain, as will be seen from the following returns, in which is stated the progressive increase of this trade from 1740 to 1827, and the proportional quantity furnished by the different iron works of the Kingdom

Quantities
of iron ma-
nufactured
in different
years.

Anno	Iron made in Great Britain. Tons.	No. of Furnaces.
1740	17,000	59
1788	68,000	85
1796	125,000	121
1806	250,000	
1820	400,000	
1827	690,000	284

By this Table we find that the make of 1827 is prodigiously above any previous year. The following is a statement of the distribution of this quantity in the proportions in which it was produced at the different iron districts.

	Tons.	Furnaces
South Wales.	272,000	90
Staffordshire	216,000	95
Shropshire.	78,000	31
Yorkshire	43,000	24
Scotland.	36,500	18
North Wales.	24,000	12
Derbyshire.	20,500	14

Of this quantity three-tenths is calculated to be foundry iron. This Table shows that the Welsh furnaces are considerably more productive, as to quantity, than those of any other districts; and the difference would, probably, be even greater at the present time, as the average make of the furnaces in Wales has certainly increased since 1827.

At the pre-
sent time.

The following is a list of the quantity of iron sent down from some of the principal works in the Merthyr-district, by the Glamorganshire canal, in 1828. The particulars are supposed to be not all of them perfectly correct, though they are probably not far from the truth. They do not precisely establish the make of the different

Manufac-
tures.

works, as they only, of course, include the iron sent to the shipping port, and can take no account of home consumption, or increase and decrease of stocks at the works.

Cyfarthfa and Hirwin works ;	Tons.
Messrs. Crawshay and Co. . .	25,412
Dowlais ; Guest and Co.	25,020
Plymouth ; Hill and Co.	14,500
Pen y Darran ; Foreman and Co.	10,805
Aberdare	9,262
Gadlys	598
Bute	177
Total	85,774

In 1829, the total quantity sent down the Glamorganshire canal was 88,000 tons; and in 1830 it was rather reduced again, the quantity being 87,364 tons, distributed in the following proportions amongst the different works.

Dowlais	Tons.
Cyfarthfa, &c.	29,621
Pen y Darran	21,312
Plymouth	12,582
Aberdare	13,046
Blakemore and Co.	7,248
Brown and Co.	2,891
	664
Total	87,364

The above works do not comprise half the South Wales district, the shipments from the port of Newport being greater than those from Cardiff. The returns of iron by the Monmouthshire canal to Newport, are for

	Tons.
1829	108,000
1830	106,000

This superiority of traffic on the part of Newport to Cardiff, was by no means the case some years ago, but latterly the works of Monmouthshire have been much increased, and have given a population and an importance to that district that was before unknown. Indeed, the face of nature has been entirely changed in some places in the space of a few years, by the establishment of new works. Romantic valleys, that before were rarely traversed by a human being, are now intersected by rail-roads, and studded with rows of workmen's houses. The flourishing woods that clothed the sides of the hills, and in the winter sheltered innumerable woodcocks, are now cut down for pit timber, or blackened by smoke, which prevents the former tenants from resuming their visits; and the clear mountain streams that teemed with life, and afforded a never-failing resource to the fisherman, are now thickened and poisoned by the mineral waters that drain into them.

The statistical inquirer may perhaps be curious to learn some particulars as to the number of people supported by the manufacture of iron in South Wales. These particulars are not to be obtained with facility, from the circumstance of there being many master workmen, or contractors, at every work, who employ a number of workmen under them, whose names are not returned in the pay books. From the best information that could be obtained on this subject, the following is a statement of the number employed on a work where there are five furnaces, and a forge and mill capable of

manufacturing about two hundred tons of bar iron weekly. Each particular class of labour is here kept separate, and the numbers of women and boys are given as well as that of the men, from which it will be observed that the employment for the former at iron works is not very extensive.

	Men.	Women.	Boys.
Colliers, including road men, horse tenders, and sundry labourers . .	280	0	27
Miners, including stacking and loading the mine, road men, horse tenders, and sundry labourers . .	395	40	73
Furnaces, &c., including furnace labour, viz., keepers, fillers, refiners, cokers, pig weighers, engineers, fitters up, moulders, smiths, carpenters, sawyers, stable men, brick makers, masons, machine men, carriers, &c.	257	39	36
Forge and mill, viz. puddlers, shinglers, rollers, catchers, straighteners, smiths, ballers, engineers, bar weighers, clerks, &c.	145	5	55
Agents, overlookers, and others, not included in the above	31	0	0
Total	1108	84	191

From the above statement it appears that five furnaces, with a corresponding establishment for the manufacture of bar iron, provide *direct* employment for near fourteen hundred individuals. Supposing in round numbers that a work of this size produces a twentieth of the iron made in South Wales and Monmouthshire, which supposition will not be far from the truth, and supposing, likewise, that the number of work people here stated affords a tolerably fair average, the iron works in this district give direct employment to about 28,000 people, to say nothing of the wives and families who derive their support from the labour of the men, and the much larger number who are necessarily employed and maintained in a variety of ways in every populous district.

It will be seen by a reference to the canal returns of bar iron sent to Newport and Cardiff, that a work producing about two hundred tons a week may fairly be stated to form a twentieth of the whole production of South Wales; and this calculation is confirmed by the following Table of the number of furnaces, which shows a proportion of nearly one to twenty in a work consisting of five furnaces compared with the total number.

Coal
mining.

(230.) *History of coal mining.*—The first notice we find of coals being employed by artificers as fuel is by Theophrastus, who describes them as earthy substances which burn like wood-coal, and are used by the smiths. The ancient Britons had a primitive name for this fossil; and Pennant says, "that a flint axe, the instrument of the aborigines of our Island, was discovered in a certain bed of coal in Monmouthshire, so situated as to render the mineral very accessible to the inexperienced natives, who in early times were incapable of pursuing the seams to any great depths."

As to the arguments that have been used to prove that the Romans, while in possession of this Country, were ignorant of the use of this species of fuel, (namely that they had no name for it, *carbo* being always used for charcoal,) we cannot consider it to have very great weight; and we believe all that can be said on the subject is, there is no proof that it was employed by them for the purposes of fuel, and no notice of it by Cæsar in his account of this Island. Some writers, however, maintain that there is great reason to conclude that certain coal mines were worked by the Romans, but their reasoning seems to be equally inconclusive with those who argue on the other side. One of the grounds on which this side of the question is maintained is, that in the West Riding of Yorkshire there are many beds of cinder in which Roman coins have been found, and a statement is made by Horsly, that there is reason to believe a certain colliery at Benwell was actually worked by the Romans, but whatever reason that may be is not stated.

There seems better authority for supposing that the Saxons knew the use of this fuel, but no notice is found any where recorded of it during the usurpation by the Danes, nor indeed for many years after the Norman conquest.

The first Charter for the license of digging coal was granted by Henry III. in the year 1239; it was there denominated sea-coal; and in 1281, Newcastle was famous for its trade in this article; but in 1306, its use was prohibited in London, from its supposed tendency to corrupt the air. However, soon after this it was used as a common fuel in the King's palace in London, and, in 1325, a trade was opened between France and England, in which corn was imported and coals exported. In the year 1379 the first duty of sixpence per ton was imposed upon ships coming from Newcastle with coals. At this period, the inhabitants of the County of Durham had obtained no privilege to load or unload coals on the South side of the Tyne; but in 1384, Richard II., on account of his devotion to Cuthbert, the tutelary saint of Durham, granted them license to export the produce of their mines without paying any duties to the Corporation

of Newcastle; and in the year 1421, it was enacted, Machinery. that the keels or lighters carrying coals to the ships should measure exactly twenty chaldrons, to prevent frauds in the duties payable to the King.

About the middle of the XVth century, Eneas Sylvius, afterwards Pope Pius II., visited this Country; and he remarked, that the poor of Scotland received for alms pieces of stone, which they burnt instead of wood, of which latter fuel the Country was very destitute. The best coals were sold in London about the beginning of the XVIth Century at the rate of four shillings and one penny per chaldron, and at about two shillings and sixpence at Newcastle; in 1563, an Act was passed in Scotland to prevent the exportation of coals, which had been the cause of a great dearth of fuel in that Country. In 1582, Queen Elizabeth obtained a lease of a great part of the mines of Durham for ninety-three years, at the annual rent of £90, which occasioned an advance in the price of coals. This lease was afterwards assigned to Thomas Sutton, the founder of the Charter House in London, who assigned it again to the Corporation of Newcastle, for the sum of £12,000, and the price of coals was immediately advanced to seven and eight shillings per chaldron. But notwithstanding these several advances upon this article, when Queen Elizabeth demanded the arrears of twopence per chaldron, which had been granted to Henry V., but the payment of which had been neglected by the Corporation, they petitioned for a remission of the debt on account of their inability, which was granted, and also a Charter to incorporate a new Company called *hostmen*, or coal-engrossers, for selling all coals to the shipping; in consequence of which the Corporation imposed one shilling per chaldron additional upon this article.

The Lord Mayor of London at this time made a complaint to the Lord Treasurer Burleigh, that the free hosts in Newcastle, to whom, for the use of the town, the grand lease had been assigned, had transferred their rights to a few persons, who engrossed all the other collieries, and he requested that the price of coals should not exceed seven shillings per chaldron, and that these collieries might be free. Up to this time, 1600, it does not appear that any mechanical means, beyond that of manual labour or the employment of horses, had been had recourse to for raising the coals from the pits, which had not yet, perhaps, attained to any considerable depths; but at this date a predecessor of the first Earl of Balcarras invented in Scotland an engine for drawing the water and coals out of the coal mines, and he obtained from James IV. a patent for twenty-one years; but this improvement was not till some time after adopted in the neighbourhood of Newcastle. In a petition of grievances, presented by the House of Commons to King James in 1610, a complaint occurred of a late imposition of one shilling per chaldron on sea coal, raised in Blyth and Sunderland, not by virtue of any contract or grant, as on the coals of Newcastle, but under the mere pretext, assumed by the contractors, of his Majesty's Royal prerogative. This petition displayed so strongly the rapacity of that body of men, and the distress occasioned by it to the inhabitants of London, that the prayer of the petition was immediately complied with; and an information was exhibited in the Star Chamber, during the same reign, by the Attorney-General, against the Mayor and Burgesses of Newcastle, by the name of *hostmen*; for that they, having the preemption of coals for the inheritors in Northumberland and the County of Durham, by their Charter of the 42d of Elizabeth, forced ships to

Manufac-
tures.

take bad coals, amongst which was a quantity of slate; for this they were fined to the amount of one hundred pounds each, and committed to the Fleet prison: the decree, moreover, was ordered to be read in the open market in Newcastle on two several market days.

In 1615, four hundred sail of ships were employed in the coal trade of Newcastle, one half of which supplied London, and the rest the other part of the Kingdom; the French traded to Newcastle at this time for their coals in fleets of fifty sail at a time, serving the ports of Picardy, Normandy, Bretagne, and as far as Rochelle and Bourdeaux; while the ships of Bremen, Embden, Holland, and Zealand were supplying the inhabitants of Flanders.

About the year 1625, another patent for raising water and coal from the mines was granted to one David Ramsay, but the particulars of it are not described, and at this time wooden railways begun to come into use, for transferring the coals from the pits to the staiths, where they were put on shipboard.

From this time to near the middle of the following century we find but little information relative to any new mechanical assistance given to the miner; this whole period of nearly one hundred years being only prolific in producing various impositions of duty by the Government, and of unauthorized demands by the Mayor, Corporation, hostmen, and others; of prosecutions, fines, imprisonments, &c.; circumstances of but little interest at this time, and, therefore, a simple statement of a few of the more prominent facts will be sufficient.

In 1630 a duty of five shillings per chaldron was enforced for all coals for exportation; and a further sum of one shilling and eightpence, if the exportation was effected by any Englishman.

In 1634, the above duty appears to have been repealed, and a duty of four shillings per chaldron laid on coals exported to foreign ports.

In 1637, an impost of one shilling per chaldron was laid by the Mayor and Corporation of Newcastle on the vend of coals for exportation.

In 1667, coals were sold in London at thirty shillings per chaldron, and an Act or order of Parliament was made at this time, prohibiting their being sold at a higher price before March 25, 1768.

This year, in consequence of the fire in London, one shilling per chaldron, on coals entering the Thames, was granted to the Corporation of London, as an aid for rebuilding the several Churches which had been destroyed. This was afterwards raised to three shillings per chaldron, to continue for twenty years.

The same year, also, Charles II. granted to his illegitimate son, the Duke of Richmond, a duty of one shilling per Newcastle chaldron, on all coals passing coastwise from Newcastle, which he and his successors levied till the year 1800, when the Government bought the right of the then Duke for an annuity which was afterwards compounded for by the present sum of £400,000 sterling.

At the end of the XVIIth Century 1400 ships are said to have been employed in exporting yearly from Newcastle 200,000 chaldrons of coals, Newcastle measure: each Newcastle chaldron amounting to about two London chaldron; its weight being fifty-three hundred-weight.

It would be uninteresting to pursue this subject through all the fluctuations and changes of imposts which followed between this period and the commence-

ment of the XIXth Century, at which time, or soon after, the Government duty per London chaldron in the port of London was nine shillings and fourpence; but in 1824 a reduction of three shillings and fourpence took place; and finally, in 1830, the remaining duty of six shillings.

(231.) To show the gradual increase in the price of coals, from the middle of the last century in Newcastle and in London, we make the following abstract from the Report of a Committee of the House of Commons, appointed to examine into the state of the coal trade in 1830, from which it appears that

At Newcastle the average price per London chaldron was in

	£.	s.	d.
1771	0	6	9
1794	0	9	6
1800	0	11	0
1828	0	14	0

And in London the average selling price per chaldron was in

	£.	s.	d.
1788	1	10	4 $\frac{3}{4}$
1790	1	12	9 $\frac{1}{4}$
1792	1	10	9
1793	1	15	0 $\frac{3}{4}$
1795	2	1	10 $\frac{1}{2}$
1797	1	15	2 $\frac{1}{2}$
1799	2	2	0 $\frac{3}{4}$
1800	2	12	3 $\frac{1}{2}$

These being the prices in the Pool, independent of any expense subsequent to their arrival.

And the charges to which every chaldron of coal was liable, after the reduction of duty in 1824, is thus stated in the same report for coals brought from the rivers Tyne and Wear.

Particulars of the Charge of One Imperial Chaldron of a Cargo of Coals from the Tyne delivered in London, sold at £35 per Score of Twenty-one Chaldrons, with 8d. Metage, and 1d. Market Dues per Chaldron. Measured out 222 $\frac{1}{4}$ Chaldrons.

Loss to seller for ingrain	0	1	8		
	1	15	9		

After these charges on the coals in the Pool, they are subject still to the following further expense for whippers, who take the coals from the vessel, (see Art. 6.) and for meters and meters' men, &c.: these charges are thus stated:

	£.	s.	d.
For every score of 21 chaldrons the ship meter receives	0	3	6
Ditto for food per day	0	3	0
In lieu of sample (per ship)	1	1	0
These payments are made by the ship,—			
A payment to City of London per chaldron	0	1	
A payment to Custom House	0	0	½
and 3d. additional for each certificate made out			

It further appears that, in 1829, in which year there had arrived in the Pool 7021 ships with coals bearing 1,503,581 chaldrons,

	£.	s.	d.
The meters received	33,690	19	4
Meters' men at 3s. per score chaldron .	11,951	17	0
Nine whippers, each ditto.....	107,566	13	0

Many of these dues, and certain restrictions with which the trade was embarrassed, have been however removed, as also the duty of six shillings per chaldron, whereby the commerce in this important article has been rendered more free, more cheap to the consumer, and not less profitable to the mine proprietor.

Having above stated such particulars as appeared deserving of notice recording the charges on coals, the different imposts and restrictions to which the trade was subject, but the greater number of which are now judiciously removed, it will be well to show the increase which has for several years been observed in the consumption of this article in the Metropolis. This will be seen in the following Table.

TABLE showing the Import of Coals for each Year, Machinery. during Twenty-eight Years, commencing 1801; also the mean Annual Rate of Increase, and the Population of the Metropolis at three different Periods.

This extraordinary export of coal is of course wholly independent of the inland consumption, of which latter, perhaps, not less than 3,000,000 tons are employed in our iron works only, besides numerous other works. Including therefore these, and private inland consumption, we have no reason to doubt the probable accuracy of the estimate stated by Mr. Taylor, in his evidence before the Committee of the House of Lords, *i. e.* that the whole consumption of coal in Great Britain amounted to the enormous quantity of 19,540,000 tons annually, exclusive of foreign exportation.

This estimate is made out as follows:

	Tons.
The annual sale of coals carried coastwise from Durham and Northumberland	3,300,000
Home consumption one-fifth	660,000
Total	3,960,000
This quantity supplies about 5,000,000 persons, which, supposing the whole population 15 millions, must be tripled	11,880,000
Consumed in iron works, and in mines of Cornwall	3,000,000
Total consumed in Great Britain	14,880,000
Exported to Ireland	700,000
Total United Kingdom	15,580,000

(232.) This extraordinary annual consumption naturally led to inquiries by the Committee, of the present extent of unworked coal in the Kingdom, and the probable time they may last, supposing the present demand to remain constant. Mr. Taylor stated, that he computed the time requisite to exhaust the supplies furnished by the Durham and Northumberland district exceeded 1700 years; but this estimate was considered by Professor Sedgwick and Dr. Buckland to be very much overrated, many of the parts included in Mr. Taylor's map being, as stated by them, wholly barren of coal, and in other parts of it there was not sufficient evidence of coals existing. Dr. Buckland being asked if he was aware of the waste of coals arising from the regulations established at the mines, and whether the extent of our unworked coal was such as to render such waste unimportant in a national point of view, replied, "that he had always considered such waste as a national calamity; it appeared to him (the witness) that we were wasting unnecessarily, that which it was the duty of the nation to preserve for the use of posterity." Dr. Buckland being afterwards referred to the following extract from Mr. Bakewell's *Geology*, in which the time the Durham and Northumberland coals will last is estimated at only 360 years, was asked if he thought the period underrated. He replied, "he did, and that he should rather be disposed to say that 400 years is a more probable estimate." The quotation in question is as follows.

"We cannot but regard the exhaustion of our coal beds, as involving the destruction of a great portion of our private comfort and national prosperity, nor is the period very remote when the coal districts, which at present supply the metropolis with fuel, will cease to yield any more. The number and extent of all the principal coal beds in Northumberland and Durham is known, and from these data it has been calculated that the coal in these Counties will last 360 years. Mr. Baily, in his survey of Durham, states that one-third of

Machinery
Annual consumption in Great Britain.

Probable time the coals of England may last.

Manufactures.

Machinery.

the coal has been already got, and that the coal district will be exhausted in 200 years. It is probable that many beds of inferior coals, which are now neglected, may in future be worked, but the consumption being greatly increased since Mr. Bailey published his survey of Durham we may admit his calculation to be an approximation to the truth, and that the coals of Durham and Northumberland will be exhausted in a period little exceeding what is above stated." Dr. Thomson, in the *Annals of Philosophy*, has calculated that the coal of these districts, at the rate of consumption going on when he wrote his Paper, will last 1000 years; but his calculation Mr. Bakewell considers to be manifestly erroneous, and, correcting certain errors which he points out, he concludes that Dr. Thomson's own estimate must be reduced, according to his own showing, to 360 years.

It cannot, Mr. Blakely observes, be deemed uninteresting to inquire what are the repositories that can supply the metropolis and the Southern Counties with fuel when no more can be obtained from the Tyne and the Wear. The only coal fields of any extent, on the Eastern side of England, between London and Durham, are those of Derbyshire and those in the West Riding of Yorkshire. The Derbyshire coal field is not of sufficient magnitude to supply, for any long period, more than is required for home consumption and that of the adjacent Counties. There are, however, many valuable beds of coal in the Western part of the West Riding of Yorkshire which are yet unwrought, but the time, Mr. Bakewell thinks, is not far distant, when they must be put in requisition to supply the vast demand of that populous manufacturing district, which at present consumes nearly the whole produce of its own open mines. In the Midland Counties, Staffordshire possesses the nearest coal district to the metropolis of any great extent, but such is the immense daily consumption in the iron furnaces and founderies, that it is generally believed, according to this author, this will be the first of our English coal fields that will be exhausted; and of the coals of Lancashire he reckons very little, so that, upon the whole, his estimate of the time of duration of the coal and ironstone of England is far from promising. On the other hand, by adopting the extent of the coal mines of Wales from the survey of Martin, he runs into the opposite extreme in respect to the coal of that district, estimating it to be adequate to supply all demands for 2000 years after the English coals are exhausted. Here, however, he falls into precisely the error he accuses Dr. Thomson of, in Durham and Northumberland, that is, accounting upon a thickness exceeding what can be made available, and not allowing for points where the coals crop out. The most correct view, in all probability, of the extent of coals in this district, is contained in a letter from Rev. Mr. Conybeare to Mr. Warburton, published in the Report to which we have so often referred. The coal measures, according to Mr. Conybeare's statement, do not lie horizontally within the limestone basin as assumed by Martin, but in a trough shape, being deepest towards the middle, and rising upwards towards the upper limits; the ends of the several seams *cropping out*, as the miners term it, that is, appearing successively at the surface. They do not, however, form one uniform sweep or inverted arch, but present a section resembling that shown in fig. 3, pl. xvi.

There are thus two basins, the one lying to the North, the other to the South of a high ridge, which runs from

Aberavon, half a mile North of the Avon, by Cefn Eglwysillan, two or three miles North of Caerphilly, a little beyond which it disappears. In the Northern basin, which is by far the most extensive, the strata are much less inclined than in the Southern basin; for in the former the dip of the strata is generally under 10° , while in the latter it is often 45° and upwards. The whole coal field is traversed by *dykes* or *faults*, generally in a North and South direction, which throw all the strata from 300 to 600 feet up or down. On the Western termination of the basin, in St. Bride's Bay, the strata exhibit the most extraordinary marks of confusion and derangement, being vertical and twisted in every possible direction.

The extent of this coal field, and the thickness of the seams, have been variously stated by different authors; but the estimate which is perhaps the most to be relied upon, is Mr. Conybeare's, who makes three great divisions of the coal seams, the lower, middle, and upper series; and he assigns to them, respectively, the average thicknesses of thirty-five, fifteen, and ten feet, making altogether sixty feet of workable coal. Martin, who described this coal field, makes them amount to ninety-five feet; and Mr. Conybeare thinks that Martin does not overstate the amount, provided all the seams be taken into the account. But Mr. Conybeare's calculation only includes the workable coals, and he considers that those seams cannot be worked with profit where it is necessary to go lower than 200 fathoms, or 1200 feet, for beyond this the expense of drainage, &c., becomes enormous. Keeping the same considerations in view, Mr. Conybeare makes the following estimate of the area occupied by the coal seams:

For the lower series, 525 square miles, at 35 feet thick.

"	"	100	"	17	"
"	middle series,	360	"	16	"
"	upper series,	64	"	10	"

This, it is calculated, after deducting one-half for loss and for what has been already worked, will amount to about 11,423,750,000 tons; and taking the annual consumption of all England at 15,000,000 of tons, the provision of good coal in the South Wales basin is sufficient for 760 years. This, with the 400 years agreed to, as the probable duration of the Durham and Northumberland coals, both by Professor Sedgwick and Dr. Buckland, gives a period of nearly 1200 years, and adding all other English sources, there can be little doubt of an abundant supply for 2000 years.

Moreover, we have hitherto spoken only of the coal fields of England and Wales, and have taken no notice of the large deposits which exist in Scotland. Nearly all the valuable mines in that Country are in the Lowlands, between the Highlands on the North and the range of slate mountains which run in a North-East and South-West direction across the island, in the South of Scotland. The Capital is very abundantly supplied with excellent qualities of coal brought from a distance of only a few miles, and delivered in Edinburgh at from nine to twelve shillings per ton. Glasgow is surrounded with collieries, and is supplied at even a cheaper rate than the Capital; and to this profusion of fuel not only Glasgow but Paisley, and the neighbouring manufacturing towns, owe, in a great degree, their origin and prosperity. The mines in the Counties of Fife and Clackmannan also produce very fine qualities of coal.

The coal formation of Scotland is found in the County of Antrim, on the opposite coast of Ireland. The col-

Manufactures.

Discovery of an old coal mine in Ireland.

Numerous coal fields in Ireland.

lieries of Ballycastle, on the North coast of Antrim, were formerly considerable, sending from ten to fifteen thousand tons to market yearly; but they are now greatly fallen off.

(233.) A very extraordinary discovery was made at these collieries about the year 1770: the miners unexpectedly discovered a passage cut through the rock, which was very narrow, owing to incrustations formed on its sides; but, on being sufficiently widened, some workmen went through it, and found that it led to a gallery which had been driven forward many hundred yards into the bed of coal. It branched out into thirty-six chambers, where the coal had been worked out in a regular manner, pillars being left at proper intervals to support the roof. Some remains of the tools, and even of the baskets, used in the works, were discovered, but in such a decayed state that, on being touched, they fell to pieces. There does not exist the most remote tradition of such a work in the Country; and its great antiquity is proved by the sparry incrustations on the sides and pillars of the mine, for, in such a situation, a very long period would probably elapse before these would be deposited. (See Hamilton's Letters on Antrim.) In the Eastern part of the County of Tyrone, at Coal Island and Dungannon, a coal formation occurs associated with that variety of limestone which is usually found underlying or alternating with the coal measures in Scotland and England.

(234.) But coal has been discovered in greater or less quantity in seventeen Counties of Ireland. The coal district of the Province of Munster, according to Mr. Richard Griffith, an experienced Geologist and practical engineer, is greater in extent than any in England, and probably contains, he says, almost inexhaustible beds of coal. It extends over a part of the County of Clare, over a considerable portion of the Counties of Limerick and Kerry, and a large part of the County of Cork. But the quality of the coal is quite different from either the English or Scotch coal, being that variety called anthracite, which burns without flame, and approaches to the nature of charcoal. It is chiefly used for burning the limestone in the adjoining districts; and the most considerable collieries, those of Dromagh, have yielded 25,000 tons per annum, at from ten to fifteen shillings per ton. The district of Clare belongs to the true coal measures, but they are chiefly the shales, sandstones, and sandy slates, coal being of very rare occurrence, as far as discoveries have yet been made, and when found it is of very indifferent quality. Mr. Griffith is of opinion that coal of a bituminous quality is very extensively distributed over the Eastern part of the Province of Connaught, particularly in the Counties of Leitrim and Roscommon; but little is as yet known with respect to the number and thickness of the seams, or the facility of working them. In the Province of Ulster, besides the collieries in the Counties of Antrim and Tyrone already mentioned, coal has been met with in the Counties of Fermanagh, Monaghan, and Cavan, but not to any great extent. The Province of Leinster contains the true coal measures, lying above the carboniferous limestone, in the County of Carlow, and in Queen's County, and in the County of Kilkenny, from whence it stretches some way into the County of Tipperary. The great deposits are around Castlecomer in Kilkenny, and Killenaule in Tipperary, and both these have been extensively worked; but according to Mr. Weaver, in his account of the Killenaule district, the coal, not only of that field, but that of the other portions

of the Leinster coal tract, is wholly of the nature of anthracite, and of a thin stratified structure.

With the prospect held out in the preceding estimates of the continuance of a supply of fuel for future years, we can have nothing to apprehend, at the same time unnecessary waste ought to be avoided, and it is expected this will be effected by the late regulations.

We now proceed to describe the working of the coals in the vicinity of Newcastle, in which we shall again avail ourselves of the very able evidence of Mr. Buddle in the Lords' Committee already referred to.

(235.) *Methods of working coals.*—When a certain tract or field of coals is to be opened, the operation is known in the coal districts by the term *winning a colliery*. The process being of course first to form a shaft, a work frequently attended with great labour and expense, at the same time that the value of the colliery, after it is won, is so doubtful, that the business is generally undertaken by a Company, who engage the colliery on lease of the proprietor, so that in case of failure, the loss being distributed, is not so severely felt, as it would be if undertaken by the proprietor himself, or any other single individual. In sinking the shaft it frequently happens water is met with in such quantities that cast-iron caissons become necessary. Mr. Buddle, in his evidence, says: One of the difficulties in sinking a shaft is passing through quicksands; another is the immense quantity of water which is met with in certain parts of the stratification, generally within forty or fifty fathoms of the surface, which has always to be dammed back by what is technically called a *tub*, that is, by the cast-iron caisson above mentioned.

In one shaft, particularly described, and which is shown in pl. xvii. fig. 3, forty feet of this cast-iron tubing was made use of, after which the ground became perfectly impervious to water. Accidents frequently occur also by the breaking of one of these caissons, in which case the water rushes down into the mine, if it be already formed, and drowns it. This of course causes a suspension of operations, and a great loss to the proprietor, till the tub can be repaired; such an accident, while only sinking, is not attended with such serious consequences, although it must necessarily, even in this case, be a great impediment. The quantity of water which thus forces itself into a shaft is such as requires a steam engine of perhaps one hundred and fifty horse power to be erected, in order to counteract this effect only. Mr. Buddle, in one part of his evidence, stated that, to sink only through one fathom of a shaft, he has known it to be requisite to erect an engine of the above power; and no sooner was this small distance passed, and the water well dammed back behind the tub, than the shaft has become comparatively dry: in such cases the expenses of a single fathom sinking may amount to a sum of £4000, while the expense of another fathom in the same shaft will not exceed, for mere workmanship, a sum of above £10. These shafts are of course carried to various depths, according to circumstances; while, as we have seen in some Countries, they are wholly unnecessary. In the neighbourhood of Newcastle the deepest working pit is one hundred and eighty fathoms, but some do not exceed twenty-three or twenty-four fathoms, but these generally yield very inferior coals. It must not, however, be understood, in stating that the deepest of these shafts do not exceed one hundred and eighty fathoms, that the coals are not

Machinery

Operation of sinking a shaft.

Pl. xvii. Fig. 3.

Manufactures. worked to a greater depth, for frequently the miners descend by inclined planes some considerable depth below the bottom of the shaft.

Ventilation. (236.) *Modes of ventilation.*—All the labour of sinking being completed, the miner now begins his work; this is done by first digging and undermining with his pickaxe at the bottom and one side into the seam or stratum of coal, as far as he can, and he then forces down great pieces by a wedge and mallet, leaving at proper intervals pillars to support the superstratum.

Before working can be commenced, however, provision must be made for ventilating the work. This is done by dividing the shaft into two by a boarded partition from top to bottom, one of the two forming the pumping shaft, and the other the coal shaft: on the coal shaft division at the bottom, or suspended in some part in an iron frame, a fire is lighted, which produces a rarefaction on that side, and consequently a draught through the pumping shaft, through the heading and up the coal shaft; but when these headings have been sufficiently extended, a second shaft is sunk, and then the ventilation is carried on by means of the two shafts, after the manner represented in fig. 11. pl. xviii. where the air is supposed to enter the shaft *a*, to be directed through the several galleries, as shown by the arrows, and finally pass up the other shaft at *b*, the direction of the current being ensured in single or double coursings by means of the partitions erected across some of the passages: these partitions are represented by the narrow dotted lines in the figure. The same figure also illustrates the new modes of working referred to by Mr. Buddle in his evidence above reported.

Different methods of working. (237.) Formerly all these pillars were left, and no greater portion of the bed was extracted than is represented by the light spaces, *viz.* about forty per cent.; but in 1795, when several collieries were nearly exhausted, according to this mode of working, attempts were made at partial working by removing one half of every alternate pillar, as shown in lower division of the figure: in this way from fifty to sixty per cent. of all the coal was extracted, and the rest was totally abandoned. These pillars, so remaining, being found to be sufficient to sustain only a roof of twenty, thirty, or forty acres, at which extent the bottom began to yield.

In 1810, another improved system was introduced. The coal mines were exhausting so fast that an attempt was made to remove every alternate pillar, and also a portion of the adjoining ones, as in the upper part of the figure; by that plan, and working in small divisions, about eighty per cent. was obtained: but an ultimate effect in these cases took place, technically denoted a *creep*, which it will be proper now to illustrate.

When the pillars first left to support the roof are lessened too much, in the way above described, a circumstance takes place we should not *à priori* expect, which is, that the foot of the pillars penetrate into the *pavement*, as it is called, or the floor of the gallery, and a slight rising is observed in the middle between two rows of pillars. This continues to increase till it arrives at a second stage, when the pavement begins to open in cracks longitudinally. In the third stage, the crack is completed, and the edges assume a sharp distinct form called metal edges. In the fourth, these metal edges, which continually rise, reach the roof. In the fifth, the edges become flattened against the roof, when the coals begin to take part of the pressure. And the last is when every thing is dead settled, and the

whole space previously excavated becomes again filled by this rising of the pavement. These several stages of the creep are shown in fig. 2, 3, 4, 5, &c.

(238.) Here all attempts at obtaining more coal must have been stopped, but for the invention of the safety lamp by Sir H. Davy, in consequence of the great danger of explosion, and the difficulty of keeping a sufficient light in such situations by the old process of the flint mill; but with the safety lamp, Mr. Buddle states, that the whole of the coals may be obtained. In the plate referred to, this ultimate process is represented. Fig. 8 shows the crushed pillars in the form last described; fig. 9 the first process of digging through the rubbish and a portion of the pillars, the exfoliation of the roof being prevented by props of timber. After going a certain length the whole of the coal is extracted, and then the roof rests for a while on the pillars formed by the flattened ridges of the creep, after which it breaks down, when all the space that had been occupied by the seam of coals is completely filled, either by the creep ridges, or by the falling down of the roof. The following figure represents the exhaustion of the whole district of its coals. A breaking down of the roof, generally extending to the surface, takes place, and the whole is closed. This is the most complete system of working, because if the coals will pay for it, they may be all obtained.

It is not necessary to enter here into any particular detail relative to the pumping of the water and raising the coals, the principle of these operations being nearly the same as in the mines already described. The principal difference is, that the coals having reached the surface, are placed in waggons, and in some instances are brought up in the waggons, and are immediately placed on a railway, and conducted to the staith to be put on shipboard; whereas the ores are left near the pit's mouth to undergo subsequent processes.

(239.) Notwithstanding the precautions taken to ventilate the mines, and the aid afforded by the safety lamp, many serious and afflicting accidents of this kind occur. On this subject Mr. Buddle was examined at some length, and we cannot do better than state his reply, as nearly as possible, in his own words. "One of the great difficulties and cause of expense and uncertainty," he observes, "to which the collieries in the above district are subject is explosion, which is common to collieries both in an open state and in a state of creep, but more particularly in working the latter, where the means of ventilation cannot be so perfect as it is in working a mine in a virgin state. These explosions are occasioned by the firing of inflammable air, either by unavoidable accidents or by the carelessness of the workmen. The inflammable air is evolved from the coal at the natural temperature of the earth, and the coals lying deep abound more in it than those lying near the surface, because there are openings at the surface by which it escapes; but in the deep mines it has no such outlets, and it accordingly accumulates in all the fissures of the stone above the coal, and a sort of natural distillation is thus constantly going on; and, consequently, if the mine is ever so well ventilated and cleared one day, it will be like a well filling with water, become charged with inflammable air the next day, or in a very short time, unless the ventilation is regularly going on." This Mr. Buddle considers the regular generation of the gas; but it is the accumulations of it which are the most dangerous. The fissures of the rock in some places are

Machinery
Pl. xviii.
Fig. 1, 2, 3,
&c.

Explosions
in coal
mines.

Manufac-
tures.

very extensive, and the communications are very distant and remote; these may be considered as natural gasometers out of which the gas, not having any outlet, is compressed by the process of distillation going on from the coal to an extent that is almost incredible; its resistance being, according to the witness, proportional to the extent of rock above it, and the thickness of the surrounding stratification, whatever it may be, stone or coal. In the course of pursuing the working of collieries into the whole coal, the miners frequently cut across the fissures, which are in the roof or in advance, full of inflammable air in a highly compressed state; and these frequently before they are closely approached break away the coal or the stone when it becomes too weak to resist, and in a very short time, even in a few minutes, from a state of apparent perfect safety, a pit becomes completely charged to the point of explosion from the immense quantity of gas rushing from these fissures, which are thereby technically called blowers; and a precisely similar effect takes place in breaking into old works; and in both cases the discharge of gas entirely overpowers the ventilation. If the proportion of gas to atmosphere is as one to fourteen, and does not exceed it, the mixture is not inflammable; but if the proportion is greater than this, the mixture becomes explosive at the first naked light it meets with. The quantities of gas discharged on these occasions cannot be estimated; but Mr. Buddle states, that in one mine in which he was viewer, it required a constant supply of 18,000 cubic feet of air per minute to preserve it in a safe working state, in consequence of the natural production of the gas only, without any reference to such cases as those above related.

In a Paper which this gentleman presented to the Philosophical Society of Newcastle, he has examined into the cause of a serious accident which occurred a few years back at the Jarrow colliery, on an occasion of the kind described above. In this case the seam of coals was broken by what is called a down-cast hitch, and before the working had quite arrived at this place an explosion took place by a piece of coal, as represented in fig. 5, being blown out by the expansive power of the gas. Here the gas was contained in the dirty, disintegrated coal between the two seams; the block of coals, five feet high, nine feet wide, and four feet thick, was thrown to a considerable distance, an explosion took place, and many lives were lost by the accident.

Steel mill.

(240.) *Obtaining light in mines.*—We have hitherto but slightly alluded to the safety lamp, but it will be proper before closing this Division, to offer a few remarks on this important instrument, and the successive steps by which it has attained its present improved form and principle of action. In the progress of mining, in cases in which it was dangerous to carry an open light, recourse was had to the steel mill, so constructed as to produce light by the collision of flint and steel. It consisted of a brass wheel about five inches in diameter, with fifty-two teeth which worked a pinion of eleven teeth. On the pinion was fitted a thin jagged steel wheel from five to six inches in diameter. Against the circumference of this wheel the sharp edge of a flint was fixed, and the tooth wheel had a handle which was turned by a boy, the whole frame having been fixed in an iron frame suspended by a leathern belt; such was the original form of this rude instrument, and such, we believe, it still continues, although it is now but seldom had recourse to. When it is used, the steel wheel is made to revolve with great velocity which thus elicits a

stream of scintillations which give a considerable light, but is of course unsteady and inconvenient; yet Mr. Buddle states in his evidence before referred to, that, prior to the year 1809, it was not unusual for him to be obliged to write and conduct much of his business underground by aid of the light thus produced.

(241.) About 1813, (see *Phil. Trans.* for that year,) Dr. Clanny, a scientific physician of Sunderland, commenced a series of experiments with a view of insulating the gas which might explode in a lamp, and thus to cut off its communication with the surrounding air in the mine. With this intent he constructed a lamp in which the combustion of the oil or tallow is supported by the ordinary air of the coal mine supplied by a pair of bellows, and passing through a stratum or reservoir of water below the light, at the same time a portion of the air already in the lamp is driven through another reservoir in the upper part above the light; and thus the air supplied may explode within the body of the lamp, without communicating the flame to the external air, however highly it may be charged with carburetted hydrogen gas. The moment the air enters the lamp it comes in contact with the flame, and consequently only a small portion of it can explode instead of the whole content of the lamp, by which means several obvious advantages are secured. The air passing by a quick current close by the flame carries the snuff with it, so that the light is always clear and steady. The other parts are air tight, and the whole is made very strong, defended by thick glass to prevent its being broken by common accident, and it was as much within the management of a boy as the old steel mill. It was, however, by no means generally introduced; hundreds of lives were sacrificed; the evil from explosion remaining almost wholly unabated. At length a Society being formed in 1813, with a view to preventing accidents in mines, Dr. Gray, Rector of Bishop Wearmouth, now Bishop of Bristol, and an active partisan in the cause, consulted Sir H. Davy on the subject; and this led to the highly important invention of the safety lamp as at present employed, and to which reference has been made in the preceding articles.

(242.) This invention, see pl. xvi. fig. 6, consists in surrounding the flame of a lamp or candle by a wire sieve. The coarsest that he tried with perfect safety contained six hundred and twenty-five apertures in a square inch, and the wire was one-seventieth of an inch thick, and the finest six thousand four hundred apertures in a square inch, and the wire one two hundred and fiftieth of an inch thick. When such a lamp is introduced into an explosive mixture of carburetted hydrogen and air, the cylinder becomes filled with a bright flame, and this flame continues to burn as long as the mixture is explosive. When the quantity of air is to that of carburetted hydrogen as twelve to one, the flame of the wick appears within that of the fire-damp; but when the ratio is as seven to one, the flame of the wick disappears. When the thickest gauze is used, it becomes red hot, and yet no explosion takes place.

In some subsequent researches on the combustion of gaseous mixtures, Sir H. Davy proposes to supply the coal miners with light in mixtures of fire-damp containing too little air to be explosive, by means of a small cage made of platinum wire one-seventieth or one-eightieth of an inch thick. If the flame should be extinguished by the quantity of fire-damp, the glow of the metal will be sufficient to guide him; and by placing the lamp in different parts of the

Machinery

Dr. Clanny's safety lamp.

Safety lamp b:
Sir H. Davy.
Fig. 6

Manufactures. gallery, the relative brightness of the wire will show the state of the atmosphere in these parts.

This beautiful experiment gave rise to Mr. Ellis's *lamp without flame*, in which a coil of platinum wire, the hundredth part of an inch thick, heated red hot, and held above a glass containing ether, or alcohol, will retain its red heat, and even reach nearly a white heat, by the invisible combustion of the alcoholic or ethereal vapour. A thin sheet of platinum or palladium produces the same effect.

A more particular account of the safety lamp will be found in the volumes of the *Philosophical Transactions* for 1816, 1817, and in Sir H. Davy's *Treatise On the Safety Lamp for Coal Miners, with some Researches on Flame*, London, 1818.

Application of the Steam Engine to Navigation.

(243.) The discovery of this application is one of those extraordinary events which occur but very rarely in the History of Science, and which, when they do occur, are calculated to alter all the existing relations of Nation with Nation, and to produce their effect in every civilized part of the Earth. The aid afforded to navigation by the introduction of this power has already produced the most important results; voyages are now made by sea with a speed, facility, and constancy, which is scarcely exceeded by our most regular land communications. Steam vessels are daily leaving our outports, which convey the mails, packages, and passengers to various ports on the opposite side of the Channel; to others, in the Baltic, to Portugal, Spain, Gibraltar, and to the Islands in the Mediterranean, whereby a correspondence is kept up between these distant parts, with a regularity highly gratifying in private life, and of the greatest importance in all commercial and political transactions. One or more passages have been effected between the Continent of America and England; another from England to India; and there is great reason to hope that a few years will render such voyages no uncommon occurrences. At present, these vessels have been but little employed for the purposes of war, but there can be no doubt, whenever this Country shall be again called upon to show her power, that steam vessels will be found of the utmost importance: they may never perhaps become fighting ships, but in towing others out of ports and harbours, or into action, in conveying troops, in removing or transporting military stores, and in bearing despatches and intelligence, they cannot fail of acting a most important part; and the numbers we are annually adding to those already in the Royal Navy, is a sufficient indication, that their value is duly appreciated by the members of the British Government. These considerations will lead us to enter at some length into a description of this important application of steam power.

History of steam navigation.

First projected by Hulls.

(244.) *Historical sketch of the progress of steam navigation.*—It appears that Captain Savery himself entertained some idea of employing the steam engine on shipboard, by propelling a paddle wheel with water raised by pumping; but in the form in which his engine existed in 1702, this can scarcely be considered in any other light than the exuberance of fancy. There is, indeed, no question that the first plausible idea of this kind is due to Jonathan Hulls, who, on the 21st of December, 1736, obtained a patent for what may be strictly considered a steam vessel. The letters patent, and a description of this boat, illustrated by a plate, was

published in a Tract by Hulls, in 1737, under the following title, *A Description and Draught of a new invented Machine for carrying Vessels or Ships out or in of any Harbour, Port, or River, against Wind or Tide, or in a Calm*. As the origin of the invention of steam boats has been strongly contested, this pamphlet, which it is now very difficult to obtain, has been brought forward to prove that Jonathan Hulls was the first person who suggested the power of steam as a means of propelling paddle wheels.

Machinery.

In describing his mode of producing a force sufficient for towing vessels and other purposes, the patentee says, "In some convenient part of the tow boat, there is placed a vessel about two-thirds full of water, with the top close shut; this vessel being kept boiling raises the water into steam, which being conveyed through a large pipe into a cylindrical vessel, and there condensed, makes a vacuum, which causes the weight of the atmosphere to press on the vessel, and so presses down a piston that is fitted into this cylindrical vessel, in the same manner as in Mr. Newcomen's engine, with which he raises water by fire.

"It has been demonstrated, that when the air is driven out of a vessel of thirty inches diameter, the atmosphere will press on it to the weight of four tons sixteen hundred weight and upwards: when proper instruments for this work are applied to it, it must drive a vessel with great force."

It would be, perhaps, useless and uninteresting to describe the method which Hulls proposed for obtaining the rotation of the paddle; it will be sufficient to say that it was extremely ingenious, and was preferred by him to the crank, which is alluded to by him as applicable to the purpose.

In speaking of this first actual proposition for propelling vessels by steam, we cannot help noticing a very illiberal remark by Dr. Renwick, an American author, on the subject of steam navigation, or rather, on the steam engine in general. Dr. Renwick's *Treatise* upon the whole is very ingenious and sensible; but the author, we must think, is unjust in his remarks with reference to Hulls, whose attempt, he says, "so far from classing amongst ingenious and profitable improvements, we should rather be inclined to rank amongst those which, from their obvious impracticability, merit the oblivion into which they instantly fall." This is sufficiently illiberal, standing by itself, but to illiberality the author adds also inconsistency, when immediately before he states, in mentioning some claims of an officer named Blasco de Garay, who, according to certain records, "made at Barcelona, in the year 1543, was the author of an experiment on a vessel, which he forced through the water by an apparatus, of which a large kettle filled with boiling water was a conspicuous part." "If this be true," Dr. Renwick remarks, "and we have no reason to doubt the authenticity of the record, De Garay was not only the inventor of the steam boat, but the first who was successful in applying steam to useful purposes. He was, however, too far in advance of the spirit of his Age to be able to introduce his invention into practice." A compliment, we cannot help thinking, which is quite as much due to Jonathan Hulls as to Blasco de Garay.

In 1775 a Mr. Perier constructed a small boat, which was tried on the Seine. Its motion was slow, the engine having only the power of one horse; but it may be said to have been a successful experiment, although the practice was not continued by its inventor.

Experiments by Perier.

Manufac-
tures.

By Jouv-
fray.

In 1781, the Marquis de Jouffray built a steam boat at Lyons, of a large size, that is, 147 feet long. The current of the Saone being very gentle, was well adapted for such experiments, and became the place of trial; but as in most other first attempts, different accidents occurred, and at length the Revolution put a final stop to them, the inventor, like most others of the privileged Orders, being forced by circumstances at that time to leave France, and to seek shelter in a foreign land.

By Ram-
say, Fitch,
Symington,
and others.

About this period also, experiments on this subject were going on in America, conducted by James Ramsay of Virginia, and by John Fitch of Philadelphia; as also in Italy by M. Serratti; and in Scotland by Mr. Miller of Dalswinton, who, having seen a model of a steam carriage, invented by Mr. William Symington of Falkirk, was so much pleased with it, that he directed the inventor to make a small steam engine to work a twin or double boat. This engine having been accordingly executed and put on board a vessel, an experiment was made with it in the year 1788, which answered so well that he had another boat made on a larger scale; which he tried on the Forth and Clyde canal in 1789, which was ultimately given up in consequence of the injury done to the banks of the canal by the violent agitation of the water by the motion of the paddle wheels. The method employed by Mr. Symington for making the connection between the paddle or rowing wheel and piston, was by placing the cylinder in a horizontal position, which it was supposed would be attended with the advantage of avoiding the necessity of a working beam. The piston was supported in its position by friction wheels, and communicated its motions by means of a crank to the paddle wheels, which were placed in the middle of the boat towards the stern; and on this account it became necessary to have a double rudder connected by rods, which were moved by a winch placed at the head of the boat. The steam engine differed but little in its action from that improved by Mr. Watt. Means were also provided to reverse the motion of the wheels, and put the boat back if necessary.

A variety of other methods of applying the force of steam to the propelling of boats were now attempted. In 1795, a very ingenious apparatus was invented by Lord Stanhope, and tried by that Nobleman in Greenland Dock. In this experiment the paddles were made to resemble the feet of a duck. This plan was also attempted in America, but does not seem in either case to have answered the expectations of the projectors. A boat was tried on the Bridgewater canal, which had two wheels on each side, and an endless chain with a number of paddles attached to it passing over them. This, however, was not attended with complete success.

In 1800, Mr. Linnaker obtained a patent for propelling vessels by forcing a stream of water from the stern, while an additional supply was at the same time drawn in from the head of the vessel. This contrivance seems to have been introduced nearly a century back; and has been repeated within a few years, but the principle is altogether fallacious.

The Marquis de Jouffray returned to France in 1796, and then found that M. de Blanc had secured a patent for building a steam boat, and the former applied to Government to have the experiments stopped, being an infringement of his prior right; but the Government were at that time too busy to attend to his appeal, and M. de Blanc proceeded, but with what success does not appear.

(245.) At this time, also, Mr. Fulton was carrying on his experiments on the Isle de Cygnes, and M. de Blanc in his turn complained of the invasion of his rights. Mr. Fulton, however, stated, that it was not his intention to remain in France, and he did accordingly soon afterwards return to America. Fulton, indeed, returned to his own Country for want of proper support in Europe. It appears from a Report of the Institute of France, that he made an offer to Bonaparte, then First Consul, to employ steam boats in the flotilla which was then preparing for the invasion of England; but it was rejected. Despairing of success in the Old World, Fulton directed his attention to the New, and resolved to convey the invention which he had just perfected in the bosom of France across the Atlantic. He was encouraged in the design by Mr. Livingston, then Ambassador from the United States to the French Government. Mr. Livingston himself was the author of several plans for navigating vessels in the open sea by the agency of steam, having proposed successively to employ horizontal wheels, wheels with oblique surfaces like those of a mill, paddles like ducks' feet, scoops, endless chains, &c. The importance of steam navigation was so much felt, and the possibility of supplying the force of the wind by mechanical power so generally acknowledged in America, that in 1798 the State of New York granted Mr. Livingston a patent for twenty years, on the express condition that before the 27th of March, 1799, he would produce a boat that would go at the rate of four miles an hour. He made use of a steam engine five or six times larger than that used by Mr. Perier, and was more successful, but did not obtain the velocity required by the Legislature, because the power he applied was still too small. Fulton made use of more than treble this force, his engine having been of twenty horse power, made by Boulton and Watt, and sent out by them to America. This was soon afterwards put on board a boat built for the purpose, which commenced running in 1807, between New York and Albany, a distance of a hundred and twenty miles, which was performed in from thirty to thirty-two hours.

The account which Fulton himself has given of the first voyage, or rather of the first starting, is very expressive of the discouragement which every experimenter has found to follow some trifling interruption or impediment. In his case an accident occurred soon after the vessel was under way: the parties witnessing the attempt, although not unfriendly, expressed their fears of success; they had most of them "foreseen something of the kind," "it was a pity so much expense had been incurred," and other remarks of a similarly disheartening tendency. The repairs, however, were made, the boat again proceeded, and the doubts and fears of the party were changed into joy and congratulations. The extraordinary exhibition of this vessel, and the effect it produced in the minds of common observers, is thus described by some American Journalist.

"She had the most terrific appearance from other vessels which were navigating the river. The first steamers, as others (in America) yet do, used dry pine wood for fuel, which sent forth a column of ignited vapour many feet above the flue, and whenever the fire is stirred a galaxy of sparks fly off, and in the night have a very brilliant and beautiful appearance. Notwithstanding the wind and tide were adverse to its approach, they saw with astonishment that it was rapidly coming towards them; and when it came so near that

Machinery.

Fulton
made the
first suc-
cessful ex-
periment.

Manufactures.

the noise of the Machinery and paddles were heard, the crews, in some instances, shrunk beneath their decks from the terrific sight, and left their vessels to go on shore, while others prostrated themselves and besought Providence to protect them from the approach of the horrible monster which was marching on the tides, and lighting its path by the fires which it vomited."

It would be unjust to refuse to Fulton the glory of this successful experiment: at the same time he had competitors not far behind him in point of time, and not at all in respect to success. Only a few days' delay in the experiment of Fulton would have conferred all the honour on his Countryman Stevens. That gentleman commenced his experiments on steam navigation in 1791, and injured his private fortune considerably in his various trials. It was not, however, till 1807 that he and his son succeeded in obtaining a useful result. The exclusive privilege of working a boat in the State of New York by steam power, was granted to him who should first propel a vessel in this way at four miles per hour; and Stevens's boat effected this only a few days after Fulton's experiment, and totally independently of him. Being, however, by the conditions shut out from the privilege of working his boat in the State of New York, he adopted the bold measure of conveying his vessel to the Delaware by sea; and thus the boat so near reaping the honour of the first prize, was, in fact, the first to navigate the ocean by the power of steam.

These voyages may be said to have been final respecting the applicability of steam to the propelling of vessels, at least on rivers; and Companies were quickly formed in America for establishing such boats on their various waters. The powers of the engines and the sizes of the boats were increased, and with them the general speed of the vessels. Success in these trials excited further undertakings; a great number of boats were already in steady employ by our Transatlantic brethren, before any good practicable steamer appeared in Great Britain; and the immense progress they have since made, may be judged from the following lists, copied from the *American Almanac* of 1832.

Steam Boats on the Mississippi.

(247.) St. Louis is 1200 miles by the course of the river above New Orleans, and is, next to that city, the largest and most commercial town on the Mississippi. In the Summer of 1831, there were six steam boats regularly employed between St. Louis and New Orleans. A trip from one place to the other and back again usually occupies twenty-four days; the shortest time in which one was ever made is eighteen days. The usual fare for cabin passengers descending twenty dollars; ascending twenty-five dollars; for deck passengers five dollars either way. Freight per 100 pounds descending twenty-seven and half cents; ascending sixty-two and a half cents.

From St. Louis to Louisville 630 miles; six boats regularly running in 1831; usual time of a trip ten or eleven days; the passage one way usually being somewhat more than three days. Fare of cabin passengers about fifteen dollars each way; deck passengers four dollars; freight about twenty-five cents per 100 pounds. One boat also runs regularly to Cincinnati, 150 miles above Louisville.

From St. Louis to Free River about 480 miles; three steam boats regularly employed in 1831; time occupied by a trip about ten days; fare for passengers ascending fifteen dollars; descending nine dollars. The route of one of the boats occasionally extended to St. Peter river, 400 miles further up.

In 1831, two boats were employed in running from St. Louis up the Missouri to Franklin, 200 miles; and to Port Levenworth 200 miles further. Freight to Franklin seventy-five cents per 100 pounds; and to Port Levenworth from 1.25 dollar to 1.50 dollar; from Franklin down twenty-five cents per 100 pounds.

From St. Louis to Pekin, on Illinois river, 180 miles, two or three boats regularly employed in 1831. Steam boats come occasionally to St. Louis from Pittsburgh.

Steam Boats and Team Boats in Lower Canada.

(248.) Plying on the St. Lawrence sixteen steam boats, four team boats. Navigating between Quebec and Montreal sixty river crafts of twenty-five to a hundred tons burden; rate of freight per ton 7s. 6d.

Square-rigged vessels on the stocks at Montreal, two; Ditto Quebec, nine; small crafts, two.

There are also two steam boats on the Ottawa river, plying between Grenville and Hull; one been La Chene and Point Fortune, and one between La Chene and the Canadas.

Steam Navigation in Great Britain.

(249.) It was not till 1812, that the first successful experiment was made in Scotland. This was a boat established on the Clyde, for the conveyance of passengers; First experiments in Scotland.

Manufac-
tures.

but even here the engine was only a three horse power. The vessel had also a great draught of water, a construction which subsequent trials have proved to be very disadvantageous. The success of this experiment, however, such as it was, led to many other trials, and it was soon seen that considerable power was necessary. Great power, however, could only be obtained by engines of a large size, which occupied considerable space in the vessel, an inconvenience, which, it was feared, at one time would be a great drawback on the general utility of the invention.

In order to reduce the space of the engine within the smallest possible compass, recourse was had to high pressure engines, and the steam was heated up to a high temperature to increase its elastic power; this led to various accidents from the bursting of the boiler. Copper, wrought iron, and cast iron were successively made use of; still, however, many accidents occurred, both in America and in England, till at length one attended with very fatal results happened on the Norwich river; in consequence of which a Committee was appointed by the House of Commons in 1817, "to consider of the means of preventing the mischief of explosion from happening on board steam boats," &c. The prudence and wisdom of this measure has since been made manifest, by the unfrequency of such accidents in English steamers, while the American Journals are perpetually making statements of the frightful sacrifice of life occasioned by a want of proper care and proper legislative enactments on this subject. At the moment we are writing we find the following list of accidents given by an American Paper, and the subsequent observations of the editor. The paragraph is as follows.

"In looking over our file of Papers for the last six weeks, we find that we have recorded no less than twelve steam boat disasters, attended with a loss in the aggregate of more than 100 lives. They are as follows: New England, boiler burst, 16 lives lost; St. Martin, burnt, 30 or 40 lives lost; Capstan, burnt, 20 or 30; Illinois, boiler burst, 13 or 20; Thomas Yeatman, boiler burst, 7; Columbia, sunk, 4; Paul Pry, boiler burst, 1; a total of 91 to 118 lives lost. George Washington, wrecked; Rapid, sunk; Black Hawk, burnt; Peruvian, sunk; Chippewa, sunk. Why is it that English steam boats are so safe to travellers, and American steam boats so unsafe? Why is it that more lives are lost on board American steam boats in one year, than on board English steam boats in ten years? Cannot the difference be partly accounted for by the fact, that in England very strict regulations are prescribed and enforced by the Government in relation to steam boats, and in the United States none? If not, can any man tell how the fact is to be accounted for?" *American Paper.*

A few days after the *American Advertiser* says:—It has been estimated that 1500 persons have lost their lives in this Country, during the past three years, by the bursting of steam boilers. Since July, 1832, (the present date June 17, 1834,) sixty-seven steam boats have been lost or abandoned on the Western waters.

How far the legislative enactments of the British Parliament may have been instrumental in producing the degree of safety which is experienced in English steamers, it is not, perhaps, easy to determine; but certainly the inquiry itself, in which the opinion of the most celebrated engineers was taken, and their attention thus necessarily directed to the subject, elicited many useful observations, and valuable practical hints, which have since

been adopted; and to these, perhaps, rather than to the enactments which followed, we are indebted for the safety in our vessels referred to by the *American Journalist*.

Seeing then the importance of this inquiry, and referring the reader to Art. 183, where the accidents to which steam boilers are liable is fully illustrated, a part of the evidence, and the various propositions and opinions given in it relative to this subject cannot be uninteresting to the reader; we therefore make no apology for giving this Abstract and Report, at some length, in the following pages.

(250.) *Mr. Bryan Donkin* was the first witness examined. He stated that he had been down to Norwich to inquire into the cause of the explosion of the steam boat at that place, and was accompanied by Messrs. Bramah and Collinge: that he was of opinion that the immediate cause of the explosion had been the use of steam of very high expansive power, and that the proximate cause was a deficiency in the strength of the end of the boiler. The boiler was cylindrical; the cylindrical part and one end were of wrought iron, the other end was of cast iron. It appeared to him to have been previously wrought iron, but that the wrought iron end had been cut off, and a cast iron end substituted in its place, and that any boiler so constructed was unsafe. He considered that the difficulty of obtaining a proper degree of strength at all times in the materials of which boilers may be made arose from the constant deterioration which such boilers must be exposed to by the action of the fire, and from the various degrees of expansion operating on different parts of the boiler, and thought there was an advantage to be derived from the use of high pressure engines, on board boats which are necessarily loaded differently at different times. This different loading requires a different power in the steam engines, and the high pressure engine is capable of having this additional power given to it, without any difficulty; whereas in the low pressure engines they are confined to the force assigned them.

Mr. Donkin being questioned respecting the saving of fuel in Woolf's engine, replied, that there is considerable saving in Woolf's engine, but in the common high pressure there is but little. He considered the length of time a boiler properly constructed, and constantly used, could be worked with safety to be extremely uncertain: had known one boiler worn out in six months, and another used for seven or fourteen years. The strength of cast iron boilers is extremely uncertain: cast iron contracts in various degrees in different parts, and therefore is liable to break: had no doubt that cast iron boilers were dangerous when used for steam of high expansive force. He thought it more practicable to make a boiler of the malleable metals to resist a high pressure, as far as the tenacity of the metals is concerned; but another difficulty occurs, which prevents the application of the malleable metals to boilers for high pressure engines, which is, that of rendering the joinings of plates secure. The witness considered that wrought iron boilers are more common than cast iron, but that cast iron would be cheaper if made of equal strength, but more liable to explosion from the frangible nature of the metal. In case of the explosion of a cast iron boiler, the metal is broken into fragments, and driven off with great violence in various directions, whereas a wrought iron boiler would give way without such effect. Generally a rent takes place, but he had seen one instance of a wrought iron boiler, where the whole of the upper part was rent from the bottom, driven through the house in

Machinery.

Parliamentary inquiry on the safety of steam vessels.

Manufac-
tures.

which it was placed, and carried to a considerable distance, but had never heard of an explosion of any consequence of a low pressure boiler, merely the giving way of the plates from wear, but not such a bursting as could be called an explosion. The feeding of low pressure boilers by a column of water, is a great means of their safety, but they ought to have a safety valve besides. Low pressure boilers, employed in boats, are not fed by a column of water; it would be inconvenient, in consequence of the motion of the vessel. Had seen very few boilers constructed for the purpose of a low pressure engine, that would sustain a pressure of ten pounds per inch, without occasioning considerable leakage, or without forcing the joints; the explosion of them, that is of low pressure boilers, is not likely to do much mischief, even when made of cast iron. The expansive force of steam, employed in high pressure engines, is very variable, from thirty pounds to one hundred and twenty upon the square inch, or even perhaps higher than that.

Instances have been known in which a boiler has been worked at one hundred and sixty and one hundred and eighty pounds per square inch. The most eligible proof boilers can be exposed to, is by water, and a pressure should be employed double that to which they are intended afterwards to be subjected. Had no doubt that Cornwall had derived an incalculable advantage from the use of high pressure engines.

(251.) *Seth Hunt, Esq.*, formerly commandant of Upper Louisiana, on his examination, stated, that in the United States a great number of steam boats had been established. The first was at New York; there were then running between New York and Albany ten boats; two between New York and the State of Connecticut; four or five to New Jersey; besides the ferry boats that pass and repass across the river, of which there were three or four; those boats work all by low pressure engines; no accident has ever happened to any one of them; they have been running since the year 1807; and the boats at Albany perform about forty trips each per annum. They go up the distance of a hundred and sixty miles in twenty-one hours, and come down in nineteen; sometimes a little longer, but never shorter than nineteen. Some of them went about seven miles an hour in still water; some boats have gone nine, ten, or eleven knots, but that is under particular circumstances. They have come from Newhaven to New York, ninety miles, in six hours and a half, without any sail. They have a sail and a mast, which they can lower down and raise up to take advantage of a favourable wind to assist them in their passage. Those which go to Albany pass up the North River, and the others to Connecticut pass through what is called Long Island Sound, which is forty miles broad in one part of it. On the River Delaware there are a number of boats also established, which ply between Philadelphia and Trenton, in New Jersey; and Philadelphia and Bordenton, in New Jersey; also others between Philadelphia and Newcastle, and Philadelphia and Wilmington; besides ferry boats which pass and repass the Delaware. Several of those boats have low pressure engines, others have high pressure engines, from one hundred to one hundred and forty pounds the square inch, and as high as one hundred and sixty; but those engines are constructed upon Oliver Evans's plan, called the Columbia plan. There are no cast iron boilers in America: the witness presumed that might arise from their not having founderies in which they can cast them sufficiently large;

VOL. VII.

they are all wrought iron boilers or copper; all those Machinery, which have to pass through salt water are copper. The boat Etna, which passes between Philadelphia and Wilmington, is a high pressure engine, and outstrips all the other boats. There is no competition at all between them. There are boats from Baltimore to French Town and back, regular boats, two lines of boats; one leaves Baltimore one day, and the other the next; they pass every other day alternately. There are other boats from Baltimore, which go to Norfolk; there they pass a still wider part of the Chesapeake, which may be sixty miles wide. They have been to New London, which is still more exposed; and have been up to New Hertford. Those were low pressure engines. On the Potowmac there are also steam boats, and on the James River, which pass between Richmond and Norfolk. The largest boats in America were those on the Mississippi, the Etna and the Vesuvius, which ply between New Orleans and Natchez; they are four hundred and fifty tons, and carry two hundred and eighty tons merchandise, and one hundred passengers; seven hundred bales of cotton besides the passengers are transported to New Orleans. Mr. Hunt recollected only three accidents to have happened to steam boats in America. (These have, however, increased to a frightful amount since that period, as is seen by the memorandum before referred to.)

(252.) *Mr. Timothy Bramah* was then called in and examined. Understood that the boiler at Norwich was worked generally with a pressure of sixty pounds on the inch, but might probably be worked at one hundred and twenty at the time of the accident. Should think it not equal to the working of sixty, having been only three-fourths of an inch, and a sixteenth in some places, in thickness, and it was four feet in diameter at the end; it was a flat end to the cylinder like a drum. Did not think that a high pressure engine, under any guard that can be applied to it, is a safe engine to use in a steam boat. Apprehended that a boiler upon a proper construction, of wrought metal, may be tried with a force so little exceeding that pressure which it is intended to bear, as not to incur any risk of being injured in the proof, and to have a complete surplus of strength, so as to enable it to be afterwards used without any danger. Recommended a double safety valve, to lock one up, and to have it examined once a week, or as often as might be necessary, to see that its action was perfect. Had seen many cast iron vessels burst as well as wrought iron. Observed that the wrought iron generally tears and opens out, thereby admitting the fluid to escape. It is generally the fluid which does the mischief when the wrought iron is used, and it is both the fluid and the material which do the mischief when the cast iron bursts. The effect in cast metal is, to carry the pieces of the metal to a considerable distance, which is seldom the case in the wrought metals, unless where there is any cold shut in the metal: the cast iron bursts like a shell, projecting the fragments to a considerable distance.

(253.) *Mr. John Taylor*, of Stratford in Essex, controller of a district of copper mines near Tavistock, was next examined. He was by report acquainted with the accident which had lately happened at Norwich. He stated with respect to the impropriety of cast iron compared with wrought, that he had constructed one of the first high pressure boilers precisely in the same manner with that on board the Norwich boat: the boiler was proved

2 G

Manufac-
tures.

to one hundred pounds per square inch, by the water proof; but it was commonly used with about forty pounds pressure; the cast iron end, however, broke one day with less than twenty pounds pressure of steam, the fracture being caused evidently by the heat expanding the cast iron end unequally, and being thereby kept from the form it would otherwise have assumed. The witness stated that he had seen the Wells Street engine which had exploded with such fatal consequences: it was of unequal thicknesses, badly cast, from small furnaces, and the contact of the iron not complete; it did not meet in fusion. It was intended to boil sugar; the thickness was intended to be, doubtless, about two inches or two inches and a quarter, but by inserting the core unequally, the thickness on one side was three-quarters of an inch, on the other side the thickness of the metal was two inches and a quarter, or thereabouts; therefore to the general objections to cast iron, was added a most improper construction. Understood from the men who were working there (the Frenchmen) that there had been something like a mercurial gauge attached to it, but that the mercury never fluctuated; it indicated nothing; that the safety valve was loaded down with weights which he could not collect, and therefore did not ascertain the pressure; it was probable there was a pressure of more than one hundred pounds per inch.

Besides the common safety valve, which may be at the discretion of the workman, he conceived it essential to have another, which should be under the control of the master or proprietor of the works. Boilers have been weakened very much by the water having been evaporated too low, so that the bottom begins to be acted upon by the fire and weakened. A hole having been previously bored in the bottom, where the fire acts, may be rivetted by a piece of lead, so that the lead remains perfectly secure as long as it is covered with water, but the moment the water leaves it the lead melts; the steam is blown out through the hole and puts out the fire; besides giving the signal of what is wanted, it at once puts an end to the cause of danger. Mr. Taylor considered that the mercurial gauge not only acted as a safety valve, but it has the advantage of exhibiting, during all times of the boiler's working, the state of the steam within the boiler, by the fluctuation that takes place in that column, as indicated by the index upon the surface of the mercury, and the state of that mercurial gauge is observable every moment. If the mercury becomes stationary, one would strongly suspect that the tube was stopped, therefore it would point out itself instantly that it had become not what it ought to be; the safety valve has not that advantage, as it does not indicate any thing till the steam is blown out by raising the weight.

He had not seen the explosion at Wells Street, but was upon the ruins immediately after. The effect seemed to be tremendous; it knocked down the whole building, which was a sugar-house of five or six stories high, and fragments appeared to have been thrown in every direction; and the boiler itself was shattered into a great number of pieces. He considered that if it had been a wrought iron boiler and had burst, it would not have produced the same effect. He thought that copper is the best metal for boilers, but that with good wrought iron, they may be made perfectly safe up to the estimated strength of from four to five hundred pounds pressure per inch. From his experience he saw no advantage in exceeding a pressure of forty or fifty pounds per

inch; and was of opinion that, in order to save coal. Machinery. in steam vessels, high pressure steam becomes an object of great importance if applied upon the principle that Mr. Woolf in the first place introduced; but which has been applied by Mr. Sims and some others; and was of opinion that high pressure boilers might be made with equal safety as low pressure boilers. In France, at Crusae, some very good engines were erected by Mr. Wilkinson at a large work: they were on Boulton and Watt's principle; one of them blew up and killed several persons. Had heard of other instances of low pressure boilers blown up, but these were not within his own knowledge. Conceived that the mercurial gauge, if of sufficient bore, might be applied with ease to the high pressure boilers, so as to produce safety as certainly as the column of water, which is in fact a water gauge, as usually applied to the low pressure; and there is no difficulty whatever in constructing a safety valve, so as to operate with certainty, and to be safe from any impediment which the engineer might intentionally place in the way of its operation without any considerable expense.

(254.) Mr. Collinge, in his examination, stated that he considered the cause of the explosion at Norwich to be the bad construction of the boiler, which was composed entirely of wrought iron except one end which was cast iron. He stated in respect to the material of which boilers in general should be made, that any material under very severe pressure is liable to fail, and cast iron in particular, because in large bodies it is known that the air cannot wholly escape in a state of fusion. He had occasionally had large masses of cylinders and pans to break up, and had frequently found cells where the air could not escape, so that there is no certainty as to the solidity of cast iron: there is certainly a much greater dependence upon wrought iron or upon wrought metal; perhaps it would be better to include copper. More mischief arises from the bursting of cast iron boilers, because cast iron flies off in fragments, and wrought iron, from its tenacity, only rends. He was acquainted with an accident that occurred at Malden, where a boiler, nineteen feet long, was blown off from the seat of its connection with the base. He found in making wrought iron boilers, that if he made them of metal of a considerable substance, they could not be so well united to make them steam tight; the rivets are put in hot, and when they are hammered to secure the joints they get cold, shrink, and do not fill the hole through which they have passed. He thought that safety valves do not always open at the proper pressure from causes that we cannot ascertain; that a column of mercury would be a judicious application, but it requires such an altitude as not to be very easily applicable to boats in consequence of the agitation of the vessel. He had made several boilers; found that if the plates were thick beyond the dimension usually employed for condensing engines, the seams do not prove equally steam tight. He considered that if a high pressure engine could be made with equal security, it would be more convenient on board a boat than a condensing engine, as it would take less room. Believed that the principal source of the explosion of high pressure engine boilers of cast iron, arises from allowing them to get cool too suddenly, and raising the steam too rapidly, whereby the metal contracts and expands at a period when we cannot investigate its occurrence: wrought iron is not subject to that danger. He found difficulty in making boilers steam tight, even

Manufac-
tures.

for condensing engines, where the plates were of a thickness fit to undergo high pressure; and considered, in consequence, that it was impossible to construct a boiler that would render a high pressure engine on board a steam boat perfectly safe.

(255.) *Mr. William Chapman* was of opinion, all engines, whether high pressure or low pressure, are dangerous to the passengers, unless due precaution be taken to emit the steam when exceeding a given pressure; for in low pressure engines the boilers are always liable to burst or to alter their form, when the pressure becomes superior to the resistance. All boilers but those that are cylindrical in the section, and with hemispherical ends or portions of spheres or cones or conoids, are liable to alter the form by the natural expansive force of the steam; and therefore all boilers but of those forms owe their safety to their weakness, because if weak they will alter their form without danger, and if strong, they have been known to bend the iron so abruptly as to break asunder.

He also considered that high pressure engines could only be rendered safe on board a vessel by having the boiler cylindrical, with curved ends, and the cylindric part of a limited diameter, with a competent thickness of wrought metal, either iron or copper, and the plates secured to each other by a double line of rivets. It is also requisite that there should be two safety valves, each laden with any determinate weight per superficial inch, on the narrowest part of the seat of the valve: one of those valves should be at perfect liberty to be raised at the pleasure of the manager, because sometimes it is expedient to raise it; the other should be under a cover of such a description as not to be opened at all, at the discretion of the engineer, but with sufficient apertures for the emission of the steam, and for any of the passengers to see that the valve was not made fast. It is also requisite that there should be a mercurial gauge of not less than an inch in diameter, and whose longest limb should not be greater than $2\frac{1}{2}$ for every pound per inch upon the safety valve. It is necessary, by occasional inspection, to take care that the mercury does not stiffen by oxydation, occasioned by the heat and motion to which it is in a slight degree liable: a high pressure engine thus guarded might be used in a steam boat with safety to the passengers, so long as the boiler was kept in order.

(256.) *Mr. Philip Taylor* considered the first and most material point to be attended to in the construction of high pressure boilers is, that the diameter should be small in proportion to their capacity; and that as small a proportion of the external surface of the boiler as possible should be exposed to the destructive action of the fire; and that the portion of the boiler so exposed, should be so situated and guarded, that in case of explosion the least possible mischief would arise. In the boilers which he had made use of, no portion of the boiler is exposed to the action of the fire without its being constantly covered with water; and the fire is applied under an arch of not more than two feet and a half in diameter: this provides against any extensive rent taking place in the event of explosion. The boilers he had generally employed, are constructed of malleable iron, commonly known by the name of charcoal iron, rivetted together and secured by strong wrought iron bolts. From observing the danger arising from the introduction of flat cast iron ends, he had terminated the ends of his boilers by wrought iron ones, nearly hemi-

spherical: this mode of construction, as far as his experience had gone, combines more strength and durability than any other. The precautions he had made use of to guard against the misuse of such boilers, have been by adapting to them two safety valves; one under the control of the engine man, the other secured in a strong cast iron case, locked down and loaded with such a weight as would suffer the steam to escape when it had arrived at an improper degree of expansive force. In order to add to the security given by safety valves, he in every instance attached to the boiler a mercurial column, the bore of which is proportioned to the size of the boiler; and he had considered an iron tube of an inch diameter sufficient to guard against accident, when applied to a boiler four feet in diameter and twenty feet in length, because the limit given by such a column has always been far within the limit of absolute safety. The length of the external limb of the mercurial gauge has in all cases been proportioned to the strength of the boiler and the force to be applied, taking care that the expansive force of the steam would displace the mercury long before any dangerous expansive force would arise. In order to guard against the boilers being injured by the action of the fire, from a deficient quantity of water in the boiler, he inserted a leaden rivet in such a situation that it would melt as soon as it was uncovered by the water, and produce an opening which would suffer the escape of the steam. Although he made use of boilers of this construction, he considered cast iron boilers safe, provided their various parts are made of small diameters in proportion to their capacity; such, for instance, as those constructed by Mr. Woolf.

The witness thought a high pressure engine with a boiler thus constructed would be equally safe with those called condensing engines.

(257.) *Mr. Henry Maudslay*, engineer, of Lambeth, was of opinion, that high pressure engines were not applicable to boats, because the purpose of such engines was to save water, which cannot be wanted on board a vessel; the difference between the one and the other makes no ultimate saving either in weight or expense, particularly when steam boats are properly contrived. He considered it necessary to have two safety valves, and sometimes three were used. To make it quite easy for the man to move the valve, he had a sort of bell-pull going down to the place where he stokes, to pull it up every hour if he pleased, to keep it in action; because it is clear the spindle may corrode and stick fast for want of use. Supposing it not touched once a week, it is not a safety valve any longer, because a very little friction will add a great many pounds weight to the opposition the steam ought to meet with. The witness never knew a low pressure engine unsafe, but it appeared high pressure engines had been so. He likewise stated, that if steam be raised beyond five or six pounds per inch in a condensing engine, the power of the engine will not thereby be at all increased; that wrought iron is extremely safe compared to cast iron for steam boat boilers. He should not consider himself in any danger in a boat fitted with a high pressure steam engine that had a wrought metal boiler, either of iron or copper, constructed by a competent engineer, with safety valves in proper order and a mercurial gauge, provided an experienced person had the superintendence of it.

(258.) *Mr. Alexander Galloway*, who was the next witness called, said he should certainly recommend that for steam boats, the condensing engines should be used in

Manufac-
tures.

preference to high pressure engines, for the following reasons. In the first place, the great advantage that has been promised from a high pressure engine is, that it can be worked in a situation where water cannot be procured, and therefore, under this circumstance, it is for such a situation a valuable machine; but in situations where water can be readily procured, it is not so. And in reference to the comparative price between a high pressure engine and a low pressure engine, and in reference to the space that it occupies, and in reference to the superintendence that it requires, he was decidedly convinced no economy is produced. Speaking of it as a matter of safety, it will be necessary to say, that experience has fully proved, that the maximum of force to be obtained by a condensing engine, is when the steam is rarefied from three to six pounds on the inch, the engine is by far more efficient than when the steam is more rarefied; and it will appear equally clear, that whether it be a cast iron boiler or a wrought iron boiler, or a copper boiler, the force of the engine is better performed by steam at three pounds and a half, than it is at any increased expansive force: the boiler being subject only to three instead of six pounds, it must be less liable to explode or burst at that than at an increased expansive force. He should further observe, that every man who is called to work a condensing steam engine, knows, that when his steam is at three pounds and a half, it performs a greater quantity of labour than at any other time; for if it is increased it throws a vast labour on the air pump and the condenser, and retards the engine; therefore, a man has no inducement to increase the expansive force of the steam, knowing that no useful end can be obtained by so doing. All boilers on board steam boats should have the fire in the interior of the boiler, because it is of very little importance as regards safety, whether the passengers are to be endangered by an explosion, or whether the vessel is to be weakened in its timbers or essential securities, by the improper application of the fire to the boiler; therefore, he invariably recommends, that the fire should be contained in the interior of the boiler, and that there should be an additional safety valve, which should be solely subject to the superintendence of the proprietor, and that the manager of the Machine should have no possible access to it. He should certainly recommend a wrought metal boiler in preference to a cast iron boiler. The witness is of opinion a high pressure engine, using the expansive force to forty pounds on the inch, and not beyond, would be a safe and efficient engine, provided that due caution was given to the safety valve. The mercurial gauge he considered an efficient and convenient apparatus; but on board a boat, it would be constantly in the way, and it would require a great column of mercury to make it safe, and such a quantity as would be likely to do mischief if blown up. He stated there was very little difference between the consumption of coals by low and high pressure engines; but if the two were combined, as in Woolf's engine, there was a considerable saving.

(259.) *Mr. John Braithwaite* thought that a boiler might be able to bear three times the pressure intended to be put upon it; and if it did bear that pressure, and they applied two safety valves with mercurial steam gauge, properly weighed and adjusted, (one of those safety valves should be at the will of the person about the boiler, and the other no man should be able to get at,) it would be impossible to explode it. He saw the

boiler at Wellclose Square after the accident, and also conversed with one of the men who was saved. He informed him he had carried an additional weight to put on the safety valve just before the explosion; that the mercurial gauge was plugged up, so that it was useless; besides which, instead of the safety valve being weighted equal to forty-five pounds, they added a double weight, which increased it to ninety pounds upon an inch, and the boiler was very improperly made. There is no danger in a steam engine boiler if properly constructed.

(260.) *Mr. John Hall*, engineer, of Dartford, had made cast iron boilers, had proved them by a hydraulic press made for the purpose, and had gone as high as two hundred and fifty pounds to an inch, which he thought sufficient, and no accident had occurred. It was his intention the next time to try what they would bear, and had no doubt he should find them competent to the task of bearing from seven hundred to one thousand pounds per square inch. He believed they could be made stronger than wrought iron boilers; such boilers being rivetted together cannot be so strong as those cast in a solid mass. He considered it scarcely possible that any imperfection could remain after it had undergone the pressure above described. He conceived it quite practicable to adjust a safety valve to a boiler, which should not be accessible to the engineer directing the Machinery, but which should sufficiently protect the boiler from mischief.

(261.) *Mr. Alexander Tilloch's* opinion was, that by attending to what should be attended to in every steam engine, and employing proper engineers, a steam engine would be perfectly safe, whether with high pressure or low pressure. The boilers ought always to be furnished with safety valves; and if they suspect the possibility of having a stupid man, one of the valves should be covered and out of his reach with a box over it, but perforated so that it might be seen when the steam operates on it. A mercurial valve is also very good; that is, an inverted syphon, with a column of mercury proportioned to the purposes for which it is to be employed. Apprehended no danger would arise, in case of explosion, from the mercury; because the tube is always perpendicular, and if the mercury shoots out, it goes away and falls down like rain. Was of opinion, a boiler might be made safe either of wrought or cast iron; but for great strain would prefer cast iron, contrary to the opinion of many people, and the reason he preferred it was, the same for which it is preferred in making cannon. It is not possible to get thick plates of wrought iron perfect throughout; but cast iron boilers can be made of any strength; instead of having a boiler that will stand sixty, it may be made to stand six hundred, of either wrought or cast iron. Another reason why he would prefer cast iron was, that the sheet iron corrodes much quicker, and destroys by oxydation, so that a boiler may be safe when first set up and stand its proof, but very soon become unserviceable, or at least comparatively so. Boilers should always be cylindrical, and for an obvious reason, capacity should be got by length and number rather than by diameter. In case of an actual explosion, he thought that the greatest danger would ensue from the cast iron, but that a properly constructed boiler of cast iron would be stronger, and therefore could not explode so soon. A boiler should be proved with cold water if it is to be applied to high pressure. With respect to the effect of cavities, he conceived no danger could arise from the expansion of the air in them; because these cavities must be formed when the iron is at a white heat, and,

Machinery

Manufactures.

consequently, the air in it must be then more expanded than it can ever be again in practice.

(262.) *Mr. George Dodd*, civil engineer, Oxford Street, examined. Had used boilers in his steam boats with flat sides and ends, because that figure gives the greatest cubical content in the smallest space, and compactness of the Machinery and the boiler is a desirable object in a steam boat; moreover, such boilers, properly constructed, and of sufficient thickness in the plates of wrought iron, may be safely used on board steam boats having the low pressure engines. He recollected the boiler of the *Caledonia*, London and Margate steam packet, bursting at sea, by the forcing out of three of the rivets over the furnace mouth, which extinguished the fire, but it was not productive of any injurious consequences to any of the persons on board; and the *Cork and Cove* packet boat in Ireland, with two hundred and fifty officers and soldiers on board, burst her boiler when lying along side of the transport that was receiving the troops: the bursting made a fissure or opening of nine inches by eighteen, but the steam which escaped did no injury, either to the persons on board or to the vessel. The construction of the boiler of the *Norwich* boat was, in the opinion of this witness, injudicious. On examination, he found the barrel or cylinder of the boiler was of wrought iron, rivetted together, of which part he approved; but he found that one of the ends was a flat plate of cast iron, and as these two metals, under the same degree of heat, have different degrees of expansion, he thought it by no means a perfect and secure boiler.

(263.) *Mr. Richard Wright* was of opinion, both wrought and cast iron boilers might be used with equal safety; but that in proving them, they ought to be kept under the pressure a considerable time, a quarter, or even half an hour; for sudden pressure might cause flaws in the metal which is liable to give rise to accident afterwards; but if under pressure a considerable time the action of it would be evident.

(264.) *Mr. John Richter*, sugar refiner, Cornwall Place, had attended from time to time during the whole period of the construction of the *Well Street* boiler, for the purpose of boiling sugar by means of high pressure; it is necessary in such case to have a pressure of from six and thirty to five and forty pounds per inch. When this witness saw the boiler, the bottom only was put up; he was at that time informed the dome part of it was cast, but it was not sufficiently strong; the casting of another was then in hand, which was afterwards completed. It appears, that in consequence of complaints from Constant, the Frenchman in whose house it was, that it would not do its work, and his fears in pressing it on to do so, the maker of it became anxious to show that it would, and a day was appointed for this to be done. Constant, at three o'clock in the morning, began his work, and continued boiling till about eight, but boiling with a great deal of difficulty, because he was afraid of putting the engine to the pressure he required. He gave it up; he said he would boil no more; and the men in attendance, who belonged to the engineer, went to fetch the engineer. He and his men came down, and persuaded Constant to have the fire lit again. He consented, after a great deal of difficulty, and went to another pan in an adjoining building, and there he was at work when the accident happened. They were urging the steam, and actually had put an immense weight upon the lever of the valve, so as to render it totally useless. This was ascertained by a Frenchman, who saw it, and who stated

to the man that he was doing mischief and doing wrong. He was told to hold his tongue, and mind his own business; that he knew his business, and they knew theirs; the consequence was, that immediately afterwards it blew up. After this accident, he went every day to the ruins, for the purpose of satisfying himself of what had been the cause of the bursting; and saw the excavation until the parts of the boiler, which was of cast iron, were found; and then finding parts of this boiler in different places, the seat of the boiler being where it had been placed, but the rest scattered about in different directions. He measured the thickness of different parts of it; the bottom of it was two inches and a half thick, the upright sides of the bottom one inch and a half thick; the lower part of the dome was seven-sixteenths thick, and one of the parts at which it must have burst, and where the boiler was completely defective in the casting, was less than the eighth of an inch thick; it was not thicker than a crown piece: the wonder is that it stood so long, not that it burst. The boiler was not intended to be worked above forty-five pounds per inch, and was ordered to be made to sustain the pressure of a hundred pounds. The whole house was blown to pieces, which, the witness apprehended, arose from the fragments of the boiler striking the story post, by which, the support being taken away, the walls fell inwards.

(265.) *Mr. John Steel*, engineer, of Dartford, gave it as his opinion that the proof arising from the pressure of cold water, was sufficient to ascertain the safety of a boiler, which shall afterwards be exposed to the operation of fire or of highly heated steam, because he imagined it to be a great deal stronger when heated to the extent steam will heat it; cast or wrought iron he considered to be at its greatest strength when at three hundred degrees, which he believed steam never had arrived at.

(266.) *Mr. William Brunton*, the next witness called, thought the boilers for high pressure engines could be so constructed as to become useless before they are dangerous; upon the principle of having the exterior part of the boiler independent of the flue, so much so, that while the flue is injured by the action of the fire, the exterior part of the boiler remains, as to strength, unimpaired; and he conceived that a boiler thus formed, when the flue has been worn very thin, and when exposed to a greater pressure than it could sustain, the thin parts of the flue would act as so many safety valves. *Mr. Brunton* considered it possible to construct boilers which would bear an expansive force of six hundred pounds to an inch. He recommended two safety valves, one in an iron box under lock and key, and the other open to the engine man. He also employed a mercurial gauge, or an inverted syphon, which, in the event of the steam being stronger than the mercury can sustain, it will be driven out, and the boiler thereby relieve itself. The witness was of opinion the fragments separated from a wrought iron boiler by explosion, in the same manner as from a cast iron one, and that they would be projected with equal force under the same circumstances. He knew one instance in which a wrought iron boiler burst with a high pressure of steam; and a fragment, the largest piece, was carried to the distance of a hundred and fifty feet. The witness was, however, induced to prefer wrought iron boilers, from the examination of several cast iron ones, which he found cracked or broken in the lower part, which, in his opinion, arose from the unequal tempera-

Machinery

Manufac-
tures.

ture and expansion in the interior of the boiler; this unequal temperature is caused by a quantity of water at all times under the flue, and, consequently, of lower temperature than the water above the flue; thereby causing the upper part of the boiler to expand in a greater ratio than the under part, which in his opinion caused the fractures alluded to. Mr. Brunton recommended wrought iron boilers on board steam boats, if properly constructed; but it is necessary, he observed, to have at least two safety valves; the one to be placed under the lock and key of the proprietor of the vessel, so secure as not to be accessible to the engine man, and another which he should have under his own control, the valves should be nearly flat or quite so, which he apprehended would be less liable to be fastened by the difference of temperature to which the valve and the seat might occasionally be subjected.

(267.) *Mr. Josiah Jessop* stated, if safety were the only object, he had no doubt that a low pressure boiler must be more secure than a high pressure, for although either of them in the first instance may be made secure, yet from the natural wear and tear both are liable to accidents. If an accident happen to one of high pressure, its consequences certainly would be more dangerous than that of a low pressure engine. Boilers should be made to withstand a proof of two or three times the pressure to which they are likely to be exposed; the witness recommended, as a means of preventing a boiler being used at a greater power than it was intended for, the use of an additional safety valve, to which the person who worked the engine should not have access. Malleable metals, such as iron and copper, are certainly preferable, because these do not burst by an explosion, as brittle metal does, but tear; it would in all probability rend at the joints, and if the safety valves be properly adjusted to the strength of the boiler, and so constructed as to work with perfect ease, with one of them put out of the reach of the engine man, there would be no occasion for the additional aid of a mercurial gauge.

(268.) *Mr. Alexander Nimmo* employed a safety valve in the boiler of a vessel belonging to the Dublin steam packet Company, which consisted of a hemispherical cup, with its curved surface downwards, resting upon a collar, and to the bottom of the cup a weight was hung which had previously been adjusted; by this means the valve is always steam tight in every position, yet without danger of adhering, and must be lifted by the steam when it exceeds a given pressure; but the valve may also be lifted by a chain attached to its upper side, which is inclosed within the iron case, and may be drawn by the engine man, or any person on board, but does not allow him to keep it down or to confine it. The witness was also of opinion, that it is scarcely possible to form cast iron every where equally strong, and if a part be weaker than the rest, either on purpose or by accident, it will not have the safety that would be obtained by a wrought iron boiler; but in cast iron boilers it is common to have holes, and if these be filled with some metal of different melting temperature from cast iron, more fusible for instance than that, the juncture will part first, and it may be made to tear as a wrought iron boiler would do; and again, the wrought iron is so much more liable to oxydation than cast iron, that although found very efficient at first, its strength and tenacity may be very speedily altered; for these reasons cast iron boilers have been preferred where high pressure engines have been used; and in small tubes the tenacity of cast iron can

be made greatly to exceed that which can be given to Machinery.
wrought iron in the same form.

Several other witnesses were examined, who spoke of their practical opinions on most of the above inquiries, but they are not calculated to afford any further information respecting the application of engines to vessels; we do not, therefore, abridge them, but shall content ourselves with giving the following Report of the Committee, dated June 24th, 1817.

(269.) *Report.*—Your Committee entered on the task assigned them, with a strong feeling of the inexpediency of legislative interference with the management of private concerns or property, further than the public safety should demand, and more especially with the exertions of that mechanical skill and ingenuity, in which the artists of this Country are so pre-eminent, by which the labour of Man has been greatly abridged, the Manufactures of the Country carried to an unrivalled perfection, and its Commerce extended over the whole World.

Parliamentary Report
on the safety
of steam
boat boilers.

Among these, it is impossible for a moment to overlook the introduction of steam as a most powerful agent, of almost universal application, and of such utility, that but for its assistance, a very large portion of the workmen employed in an extensive mineral district of this Kingdom would be deprived of their subsistence.

A reference to the evidence taken before your Committee, will also show with what advantage this power has lately been applied, in Great Britain, to propel vessels both of burden and passage, how much more extensively it has been used in America, and of what further application it is certainly capable, if it may not be said to be even now anticipated in prospect.

Such considerations have rendered your Committee still more averse than when they entered on the inquiry, to propose to the House the adoption of any legislative measure, by which the science and ingenuity of our artists might even appear to be fettered or discouraged.

But they apprehend that a consideration of what is due to public safety, has on several occasions established the principle, that where that safety may be endangered by ignorance, avarice, or inattention, against which individuals are unable, either from the want of knowledge, or of the power to protect themselves, it becomes the duty of Parliament to interpose.

In illustration of this principle, many instances might be given: the enactments respecting party-walls in building, the qualification of physicians, pilots, &c., the regulations respecting stage-coaches, &c., all seem to be grounded upon it. And your Committee are of opinion, that its operation may, with at least equal propriety, be extended to the present case, on account of the disastrous consequences likely to ensue from the explosion of the boiler of a steam engine in a passage vessel, and that the causes by which such accidents have generally been produced, have neither been discoverable by the skill nor controllable by the power of the passengers, even where they have been open to observation.

Your Committee find it to be the universal opinion of all persons conversant in such subjects, that steam engines of some construction may be applied with perfect security, even to passage vessels; and they generally agree, though with some exceptions, that those called high pressure engines, may be safely used with the precaution of well-constructed boilers, and properly adapted safety valves; and further, a great majority of opinions lean to boilers of wrought iron or metal, in preference to cast iron.

Manu-
factures.

Your Committee, therefore, in consequence have come to the following Resolutions; which they propose to the consideration of the House:

1. Resolved, that it appears to this Committee, from the evidence of several experienced engineers examined before them, that the explosion in the steam packet at Norwich was caused, not only by the improper construction and materials of the boiler, but the safety valve connected with it having been overloaded, by which the expansive force of the steam was raised to a degree of pressure beyond that which the boiler was calculated to sustain.

2. Resolved, that it appears to this Committee, that in the instances of similar explosions in steam packets, manufactories, and other works where steam engines were employed, these accidents were attributable to one or other of the causes above alluded to.

3. Resolved, that it is the opinion of this Committee, that for the prevention of such accidents in future, the means are simple and easy, and not likely to be attended with any inconveniences to the proprietors of steam packets, nor with any such additional expense, as can either be injurious to the owners, or tend to prevent the increase of such establishments. The means which your Committee would recommend are comprised in the following regulations:

That all steam packets carrying passengers for hire, should be registered at the port nearest to the place from or to which they proceed:

That all boilers belonging to the engines by which such vessels shall be worked, should be composed of wrought iron or copper:

That every boiler on board such steam packet should, previous to the packet being used for the conveyance of passengers, be submitted to the inspection of a skilful engineer, or other person conversant with the subject, who should ascertain, by trial, the strength of such boiler, and should certify his opinion of its sufficient strength, and of the security with which it might be employed to the extent proposed:

That every such boiler should be provided with two sufficient safety valves, one of which should be inaccessible to the engine man, and the other accessible both to him and to the persons on board the packet:

That the inspector shall examine such safety valves, and shall certify what is the pressure at which such safety valves shall open, which pressure shall not exceed one-third of that by which the boiler has been proved, nor one-sixth of that which, by calculation, it shall be reckoned able to sustain:

That a penalty should be inflicted on any person placing additional weight on either of the safety valves.

4. Resolved, that the Chairman be directed to move the House, that leave be given to bring in a Bill for enforcing such regulations as may be necessary for the better management of steam packets, and for the security of his Majesty's subjects, who may be passengers therein.

(270.) It must be admitted, and is indeed implied, in the preceding Report, that there was a greater difference of opinion between some of the witnesses in the investigation than we might have anticipated on a scientific subject. Science, however, cannot penetrate into all the mysteries which arise in practice; and hence it follows, that the predicted results of this or that untried experiment, are liable to uncertainty. We have no doubt, however, that the practice of steam navigation has bene-

fited largely from the inquiry; and it has certainly since increased to an extent which is truly astonishing, as will be seen by the following Parliamentary Return, showing the number of boats in actual service in the several ports of the United Kingdom for each year from 1814 to 1828. The first sea voyage of an English boat was made in 1815, from Glasgow to London; and in the following year a steam vessel crossed from Brighton to Dieppe. In 1820, steam vessels were first introduced into the Post Office department, as packets between Dublin and Holyhead; and about the same time two steam vessels were built for the Naval department. Since that time the Admiralty have largely increased the number of steam vessels and their tonnage; there being several at this time equal in tonnage to frigates driven by engines of 200 and 220 horse power.

Machinery.

(271.) *Official Return of the Number of Steam Vessels, with the Amount of their Tonnage, and the Number of their Men, that belonged to the several Ports of the United Kingdom, from 1814 to 1828, both inclusive, (exclusive of Government Vessels.)*

Years.	Vessels.	Tons.	Men.
1814	11	542	65
1815	25	1,558	150
1816	34	2,064	201
1817	42	2,382	233
1818	53	3,807	305
1819	60	4,155	369
1820	78	5,086	478
1821	101	8,003	712
1822	129	11,007	924
1823	151	13,104	1,112
1824	168	14,708	1,276
1825	213	18,730	1,630
1826	285	26,904	2,278
1827	318	30,239	2,566
1828	344	30,912	2,708

The following Table shows how the above 342 vessels were distributed, in respect to the different parts of the United Kingdom, in 1828.

London	57	Whitehaven	2
Beaumaris	2	Yarmouth	4
Bristol	8	Aberdeen	4
Carlisle	1	Campbeltown	2

Cambria	83	32	
Sir Joseph Yorke	61	57	Messrs. Joliffe and Banks.

We have not the means of knowing what the increase has been during the six years since 1828, but if we assume it equal to three times the increase of the last two years in the above list, the number of vessels at this time belonging to private individuals and private Companies in the different ports of the United Kingdom, will be 515, their tonnage 42,936, and the number of men employed in them 3998; or, in round numbers, 500 vessels, 43,000 tons, and 4000 men.

The largest steam vessel at present in Britain is the *Monarch*, belonging to the London and Leith Steam Packet Company; it was built by Messrs. Green, Wigram and Green, in 1833, from the plan of Mr. Charles Wood, of Port Glasgow. It was superintended while building by the present scientific commander, William Bain, Esq., a master in the Royal Navy, by whom we have been favoured with the following dimensions of the hull, and other particulars.

Length of keel	180 feet.
Over all	208
Beam for Tonnage	32
Hold	18.4
Extreme breadth	55.4

It is propelled by two engines of one hundred horse power each, constructed by Boulton and Watt. Cylinders 53 inches; diameter stroke 5 feet; extreme diameter of paddles 21 feet, floats 10 feet by 2½ feet; the average speed is 10½ miles. The voyage from London to Leith has been performed in 39 hours. The space occupied by the Machinery and the coal space measure 60 feet by 32 feet; the coal space will contain 140

tons. The weight of the Machinery and boilers is 226 tons. The average consumption of coals is 21 hundred-weight per hour.

This vessel makes up one hundred and fifty beds for passengers, and one hundred are comfortably and elegantly accommodated in the saloon at dinner.

The appointments of the vessel are as below:

Commander	1
Officers	3
Seamen	12
Engineers	2
Fire men and coal trimmers ..	8
Boatswain and mate	2
Carpenter	1
Cook and mate	2
Stewards	10
Female attendants	2
Total ..	43

(273.) *On the propelling and resisting forces in steam vessels.*—It is not our intention in this place to enter into inquiries relative to the stabilities of different shaped vessels, nor to investigate the resistances which vessels offer according to their form and velocity, as this belongs rather to the *Treatise on NAVAL ARCHITECTURE*. The subject which it is proposed to treat of more particularly in this place is, the force employed in propelling the vessel: the different modes which have been proposed for effecting this object; the resistance opposed to the paddles, and the resulting velocity of the vessel itself; and as in all such cases, actual practical results are more valuable than theoretical investigation, we shall, as far as possible, draw our deductions from experiments at large.

The most general, and undoubtedly the most efficient, method of propelling vessels by steam power, is by means of paddle wheels, but other principles have been had recourse to, to which it may be well slightly to allude, including also some in which manual exertion is the motive power. The first and most simple of the latter class is the employment of oars, as in rowing. This is indeed a sort of single paddle, instead of a paddle wheel, or it may be considered as a combination of a number of simple paddles, when several persons are employed in this service. This was a method much practised by the Ancients, who had attained to great skill in their modes of combining the action of the several oars, to produce the best effective result.

The action of the oar is extremely simple, and remarkably suited to the power of a man; because, by giving to it a certain length, the muscular action requisite to give it force is precisely that which a man can exert with the least possible fatigue.

If we conceive the oar thrown on land, or on the banks of a river or canal, where it can find a fixed resistance, it obviously becomes a mere lever, where the end on the land is the fulcrum, the other extremity the power, and the *rowlock* the point at which the weight, or the resistance of the water to the motion of the boat, is applied. From this effort the boat is urged forward, and it is equivalent (as far as regards the balance of the muscular power applied) to a weight being raised to that height.

If now the oar, instead of resting on the land, has its broad side exposed to the water, and the same effort be applied, the same effect will be produced, except that, in

On the propelling and resisting forces in steam vessels.

Case of the common oar examined.

Manufac-
tures.

Action of
the paddle
wheel.

Other me-
thods of
propelling.

Machinery

this case, the fulcrum yields back more or less, depending on its action against the water, and the boat advances forward so much less each stroke of the oar, but the time of making the stroke is proportionally less, so that upon the whole the effect is the same. The resistance opposed to the boat multiplied by the length of the oar beyond the boat, being, in either case, equal to the muscular power applied multiplied by the whole length of the oar, or rather to that length as measured to the point which forms the centre of resistance.

(274.) The next method in point of simplicity, and which, although differently arranged, is the same in principle, is the paddle wheel, which was applied to the propelling boats, long before it was thought possible to give motion to those paddles by the power of steam. The principal disadvantage of this application, as compared with the former is, that as the paddle or oar now makes a complete revolution, a part of the motion is lost, not merely by becoming non-effective, but by actually offering a retarding force, tending to check the forward motion of the boat, by each paddle lifting a quantity of water on its quitting the surface. A great deal of power is thus spent in the modern steam boat, where the actions and counteractions of the paddles are so mixed and confused one with the other, that it is perhaps wholly impossible, or at least extremely difficult to separate them, and thereby theoretically to compute the effect of a given steam power in propelling forward any vessel to which it is applied. If there were no back water, and the water itself could be preserved in the quiescent state always supposed in theory, we ought to find the product of the power applied to the pistons of a steam vessel, multiplied by the space through which they pass, equal to the resistance against the paddle or paddles acting in the water, multiplied by the space through which they pass in the same time, the piston power being supposed, as it is always understood in practice, to be the power remaining after the friction and other resistances of the engine have been deducted; and these products ought again to be equal to the resistance opposed to the boat multiplied by the space through which the boat advances during each stroke of the piston. It is in vain, however, to look for these equalities in practice, the quantity of back water, the resistance of the water within the paddle box, the extraordinary commotion of the water in the immediate vicinity of the wheels, are all actions of that kind, which resist and counter-resist the wheels, the vessel, and each other, in forms and degrees of so complicated a description, as to set at defiance any effort to separate them. We have, therefore, no intention to make the attempt, but by a comparison of several well-conducted experiments, to obtain results more simple and satisfactory, and more deserving of confidence than could possibly be deduced from the most refined analysis. Before, however, we enter on this part of the subject, it may be proper slightly to mention other methods which have been proposed for effecting the same object, that is, for propelling boats and other vessels in canals, rivers, and other streams.

(275.) Of these, one method consists of a combination of parts to be kept constantly under water, and to shut up into a small space when they are moved forward, but to expand when striking backward. Another consists of inclined planes placed behind the vessel, and moved with an alternating motion, as in the case of sculling.

Again, Daniel Bernoulli proposed, in 1752, a method consisting of planes immersed in the water, parallel to

the sides of the vessel, which, turning in a collar, were to be moved in a plane perpendicularly to the keel, and thus to urge the vessel forward.

Another contrivance is a screw, resembling what is called the water screw, working in a cylinder entirely immersed in the water, or two screws or spirals working in opposite directions without a cylinder. This method was partially tried by Mr. Whytock, and is alluded to by Colonel Beaufoy, who states it to have been brought from China, and he attended to see an experiment with it on a considerable scale, made in the Geenenland Dock by Mr. Littleton. This gentleman caused to be fixed to the stern post of a Virginia pilot boat a frame containing a large copper spiral, which was worked by a winch, turned by two or more men, to give it a rotary motion; but the effect was much less than was expected; for, notwithstanding the boat was completely empty, and great exertions made, the progressive velocity did not exceed the rate of two miles per hour.

Lastly, a method, to which we have before alluded, was a pump to draw water in in front, and to propel it out behind the vessel. This was first proposed by Bernoulli, and afterwards formed the ground of a patent taken out by Mr. Linaker, but it did not succeed. These, with numberless variations and combinations of the same principles, have been proposed with the same object, but it would be useless to enter into further description. Considerable experience has now shown, that of all the methods of propelling vessels, that of oars, where manual agency is employed, and paddles where steam is the motive power, are by far superior to any others yet suggested, although it is of course impossible to say what may yet be effected by the ingenuity of Man. If we could prove that the whole agency of the steam engine was employed in overcoming the resistance of the vessel only, we should know that all had been effected which was possible; but there is unquestionably at present a great deal of power thrown away, and great room is left for the exercise of ingenuity. This has, indeed, been sufficiently prolific, in the number and variety of shapes given to paddle wheels, in order to avoid some of the evils pointed out above; but, unfortunately, many of these, which are actually in other respects calculated to effect their object in a greater or less degree, are necessarily so complicated, and contain so many joints and moving parts, as to render them easily disarranged, while they possess too little strength to resist the enormous shocks a paddle wheel has to sustain in rough and stormy weather.

(276.) It has been already observed, that the extraordinary commotion of the water in the vicinity of the paddle wheel of a steam boat is such as to bid defiance to any investigation founded on theoretical principles only, and that the only means of arriving at the requisite data, is through the medium of experiment; fortunately, the writer of this Paper has been furnished with a series of results made at Woolwich, many of which he himself witnessed, on several of his Majesty's vessels, which seem to supply all the information that can be expected on this subject.

Generally, the navy steam vessels have their engines put in and their repairs made at Woolwich dock-yard; and every vessel before she leaves this station, is submitted to experiment. In one of the reaches of the Thames, near Purfleet, an English mile is measured on the bank, and two marks are placed at each end, so that as the boat runs down the river, it is an exact mile be

Experi-
ments on
steam ves-
sels.

Manufactures.

tween the points in her passage, where the two marks at each end cover each other. The time employed in running this mile is carefully noted by a seconds' watch; the vessel proceeds about a mile or a mile and a half further, is then put about, the mile is run the contrary way, the time again noted, and the experiment is frequently repeated a second or third time. This is commonly done about the time of high water, when there is but little tide; but the effect of this, whatever it may be, is always eliminated by means of the following equations.

Let t be the time in seconds in performing the mile against the tide;

t' the time with the tide;

v the velocity in miles per hour of the boat;

v' the velocity of the tide water;

n the number of seconds in an hour;

$$\begin{aligned} \text{then } \frac{t}{n}(v-v') &= 1 \\ \text{and } \frac{t'}{n}(v+v') &= 1 \end{aligned} \quad \left\{ \begin{array}{l} \text{or} \\ \end{array} \right. \quad \begin{aligned} t(v-v') &= n \\ t'(v+v') &= n. \end{aligned}$$

Multiplying the upper equation by t' , and the lower by t , we have

$$t t' v - t t' v' = t' n$$

$$t' v + t t' v' = t n,$$

by addition,

$$2 t t' v = n (t' + t);$$

whence

$$v = \frac{t' + t}{2 t t'} n.$$

The following experiments on his Majesty's steam vessel *Dee*, will illustrate this formula. Power 200 horses; twenty-three strokes per minute.

		m.	s.	s.
1. Exp.	Time of running a mile against the tide	5	51	or 351
	Ditto with the tide	5	33	or 333
2. Exp.	Time of running a mile with the tide	4	23	or 263
	Ditto against the tide	7	58	or 478
3. Exp.	Time of running a mile with the tide	4	50	or 290
	Ditto against the tide	6	35	or 395

$$1. \text{ Exp. } v = \left(\frac{351 + 333}{2 \cdot 351 \cdot 333} \right) 3600 = 10.52 \text{ miles per hour.}$$

$$2. \text{ Exp. } v = \left(\frac{263 + 478}{2 \cdot 263 \cdot 478} \right) 3600 = 10.58$$

$$3. \text{ Exp. } v = \left(\frac{290 + 395}{2 \cdot 290 \cdot 395} \right) 3600 = 10.76$$

$$3 / 31.86$$

$$\text{Main speed } 10.62$$

In this way the actual speeds of the several vessels in the following Table have been determined, and with it is also stated all the particulars necessary for investigating the laws in question.

Table of experiments. (277.) TABLE of Experiments to ascertain the Speed of the following Steam Vessels, in which is also stated the Power of the Engines, the Diameter of the Wheels, the Size of Paddle, Number of Strokes of the Piston, &c., made by O. Lang, Esq.

NOTE.—The wheels distinguished as *Morgan's Wheels* are of a particular construction, by which the paddle is made to enter the water nearly perpendicularly, and leave it also in a like position; thereby avoiding the shock otherwise caused by the paddle striking the water on its entrance, and the back water thrown up by the common wheel on its exit.

These paddles are not always rectangular, but frequently of the shape shown in the annexed figure, and they turn on an axle in the line $a b$, which generally about bisect their area, and on which line the centre of pressure may be supposed to be situated, as they pass nearly perpendicularly through the water; whereas the common paddle, passing through the water circularly, different parts of it move with different velocities, which bring the mean centre of action below the middle. Moreover, the more

Machinery

Manufactures. remote parts act longer than those nearer the centre of motion, which brings this centre still lower. Calculation makes this point divide the depth of the paddle in the ratio of sixty-two to thirty-eight: but it will be enough for our purpose to take the ratio as three to two; and according to this proportion, the effective diameters of the several wheels given in the preceding Table, are computed and inserted in the following Table; at least in all the common wheels. Those of Morgan's construction, from what is above stated, require no reduction. Machinery

In this Table is also shown the tonnage per horse power; the area of paddle per horse power; the relative velocity of the boat, the paddle, and piston; and the computed horse power employed in propelling one vertical paddle in each wheel, and the proportion of the whole power of the engines expended on the paddles.

(278.) Table of Proportional Numbers deduced from the preceding Data.

Names of Vessels.	Ton- nage.	Horse power.	Tons per horse.	Area of paddle per horse.	Depth of paddle.	Effective diameter of wheels.		Ratio of velocity of wheel and pis- ton.	Ratio of velocity of vessel and pis- ton.	Ratio of velocity of vessel and wheel.	Ratio of the whole power to that on one paddle in each wheel.

Law of re-
sistance de-
termined.

(279.) Before attempting any deduction from this Table, it may be well to report another experiment made in the basin in Woolwich yard, on the Medea, while at her moorings. In this case, the steam being admitted upon the piston, and both wheels connected, the number of revolutions per minute was found to be $8\frac{1}{2}$; one wheel being now put out of action, the power of the two engines, that is, the same power as before, was applied to one wheel only, and the number of revolutions per hour was found to be $12\frac{1}{2}$.

Here the power expended in these two cases is evidently as the number of revolutions, and therefore the power required to move a surface a , at the rate of $12\frac{1}{2}$, is to the power requisite to move a surface $2a$, at the rate of $8\frac{1}{2}$, as $12\frac{1}{2}$ to $8\frac{1}{2}$. Let the resistance vary as the n^{th} power of the velocity; then calling $12\frac{1}{2} = V$ and $8\frac{1}{2} = v$,

$$2a v^n = \text{resistance on both paddles,}$$

$$a V^n = \text{resistance on one paddle;}$$

but in the former case the resistance is overcome with the velocity v , and in the latter with the velocity V ; therefore the whole expressions of the two effects are

$$2a v^{n+1} \text{ and } a V^{n+1};$$

but these are to each other as the forces expended; viz. as $v : V$: we have therefore

$$2a v^{n+1} : a V^{n+1} :: v : V$$

$$2a v^n = a V^n;$$

hence

$$n \log v + \log 2a = n \log V + \log a;$$

$$n = \frac{\log 2a - \log a}{\log V - \log v} = \frac{\log 2}{\log V - \log v}.$$

Substituting the numbers, we find $n = 1.8$; or the power very nearly as the square, as the theory requires. Moreover, in one case, the friction of the wheels on their axles, and of the several joints in the different parts, (of which there are more than forty in wheels of this construction,) is double in one case what it is in the other; so that if we knew what allowance to make for this retarding force, we might find n still more approximative to the index 2.

From this experiment we may then conclude, that notwithstanding the great commotion of the water in the vicinity of the paddle, the resistance on the paddle varies as the square of the velocity. The number of revolutions in this case not having been so great as in preceding experiments of a similar kind, led the engineers to expect something amiss; the cylinders were therefore uncovered and examined, and some packing was found displaced: this being corrected, and the experiment repeated on one wheel, the number of revolutions per minute was $15\frac{1}{2}$. The experiment was not tried on both wheels, but there can be no doubt if it had, the speed in this case also would have been found proportionally greater.

These $15\frac{1}{2}$ revolutions per minute being due to the engines in their best state, we may examine how much of the power of the engine can be accounted for by the resistance and velocity of the paddle.

Manufac-
tures.

Here $15\frac{1}{2}$ revolutions per minute, the wheel being 21 feet in diameter, is equal to 1023 feet per minute, or 17 feet per second. This velocity produces a resistance due, a fall of $\frac{172}{4g} = 4\frac{1}{2}$ feet.

The area of one paddle being 19, and a cubic foot of water weighing $62\frac{1}{2}$ pounds, we have

$$4\frac{1}{2} \times 19 \times 62\frac{1}{2} = 5343.7 \text{ pounds} = \text{resistance.}$$

Now this resistance is overcome with a velocity of 1023 feet per minute, and that on the piston, *i. e.* $165 \times 220 = 36,300$, with a velocity of 155 feet per minute, or their relative velocities are as 6.6 to 1; hence

$$5343.7 \times 6.6 = 35,268.4,$$

and

$$36,300 \times 1 = 36,300;$$

that is, the whole force expended on one paddle is equal to the whole force of the engines, within one thirty-sixth part of the latter, which is probably due to the friction of the wheel as above stated. Hence then we may conclude, that in Morgan's wheels only one paddle in each is effective, the vessel being moored, and that the reaction upon it is equal to the power of the engine at that time exerted, or very nearly so.

(280.) We may now explain the computation by which numbers in the eleventh column of the preceding Table were obtained.

Method of
obtaining
the propor-
tional num-
bers in the
preceding
Table.

It is assumed, that the pressure of the engine for each horse power is 165 pounds, and consequently 165, multiplied by the number of horses, is the whole pressure on the engines. Also, from the last experiment, that the pressure of one vertical paddle is equal to the pressure due to the difference of the velocities of the paddle and boat into the area of the paddle. Now denoting the latter pressure on two paddles, one in each wheel, by p , that of the piston by P , and the ratio of the velocities of the paddle and piston by $r : 1$, then the ratio of the power exerted by the engine on a single vertical paddle in each wheel, is to the whole power of the engines as $p r : P$, and the latter divided by the former give the number contained in the last column.

As an example, take the case of the Albion.

As $7 : 22 :: 12 : 37.7$ feet circumference,

$37.7 \times 27 = 1018$ feet per minute, velocity of paddle,

8.84 miles per hour = 778 feet per minute, velocity of boat,

240 feet per minute = 6 feet per second,

the difference of velocity per second, or the velocity with which a vertical paddle acts upon the water, expressed by $V - v$. Now the pressure due to this velocity on any area a , is equal to that area multiplied by the weight of a column of water on the same base or area a , through which a heavy body must fall to acquire that velocity, which by the known laws of gravity, and the weight of a cubic foot of water, is expressed by

$$\frac{(V - v)^2}{4g} \times 62\frac{1}{2} \times a = \text{pressure.}$$

In the case in question, $v = 6$, $g = 16\frac{1}{2}$ feet, $a =$ area of two paddles = 27. Therefore

$$\frac{36}{64\frac{1}{2}} \times 62.5 \times 27 = 421.$$

Hence as $r = 5.4$, in this particular case,

$$\frac{165 \times 100}{421 \times 5.4} = 6.9,$$

Machinery.

which is the number in the Table; and it expresses, that of the whole power of the engines only about one-seventh of it is expended on two vertical paddles, one in each wheel.

In examining the numbers in this last column, considerable disagreement will be found to exist amongst them, which at first sight seems to defy all attempts at establishing any law by their aid. But it will be seen by the preceding computation, that the amount of this expression depends greatly on the value of the quantity $V - v$, the difference of velocity between the wheel and the vessel, and this difference depends much upon the number of strokes made in a minute. Now the gentleman who superintended these experiments made the register of the number of strokes per minute, without any idea of their being likely to be called for as an important part of his observations. No attempt was therefore made to state the fractional part of a stroke, and indeed no very minute attention was paid to the subject. It is obvious, however, that a fractional part of a stroke per minute will largely affect the numbers in question. We therefore propose now to reverse the operation, and by assuming six for a mean number in the last column, compute the corresponding number of strokes in the engine requisite to produce it; and it will then be found that a slight correction in the strokes of the engine will be sufficient to reconcile all these apparent anomalies.

Since we have seen that

$$(165 \times \text{horse power}) + \frac{(V - v)^2}{64} \times 62\frac{1}{2} \times a \times r = \text{No}$$

we have conversely, taking $\text{No.} = 6$,

$$\frac{64 \times (165 \times \text{h. p.})}{6 \times 62\frac{1}{2} \times a \times r} = (V - v)^2.$$

And since v , the velocity of the boat in each case, is given, that of V becomes known, and hence the number of strokes per minute. This computation is made, and the resulting number of strokes, and the registered number, entered in the two adjacent columns; and it will, we think, be readily admitted, that the corrections are not greater than are fully admissible under the circumstances in which this datum was recorded. Moreover, the wind has an influence which cannot be eliminated as can that depending on the tide; and which, independently of any want of precision in registering the strokes of the engine, would account for the discrepancies in question.

Manufac-
tures.

These differences, as above stated, are generally within the limits of one stroke per minute, except in one or two cases, where the vessel was deeply laden, and in the Meteor which is not laden. The discrepancy in the loaded vessels may depend, and it indeed must depend, on their greater immersion; the wind, moreover, has a considerable effect in retarding or accelerating the motion. So that on the whole, perhaps, we may be allowed to conclude from the preceding experiments, that, in general, only about one-sixth part of the power of the two engines is expended upon overcoming the resistance of the two vertical paddles one in each wheel.

It hence appears, that in the basin, with Morgan's wheels, all or nearly all the power expended by the engine is accounted for by the resistance of one paddle, when one wheel only is employed, and on two when two are in action. But that with the common wheels, and while the boat is in motion, and both wheels acting, the resistance experienced by one vertical paddle in each wheel will not absorb, at a medium, more than one-sixth of the whole power of the engines. These are results drawn from actual experiment, and no explanation or theory of the action of paddle wheels will be considered sufficient that is not competent to account for this apparent discrepancy, which must appear the more extraordinary as there can never generally be more than three paddles acting on each wheel at the same time, and as the vertical position of the paddle has been hitherto considered the most effective.

Question
respecting
the most
efficient
paddle exa-
mined.

(281.) This last supposition is, however, extremely erroneous; and acting on this error, or at least overrating the advantage of a direct action, many persons have endeavoured to make the paddles, by various contrivances, pass through the water in a vertical position, which, though it possesses some advantages, is the most unfavourable for propelling the boat through the water.

To demonstrate this fact, let the paddle form with the vertical an angle denoted by x . Let V be the circumferential velocity of the mean acting centre of the paddle, and v the velocity of the boat; then $V - v$ will be the relative velocity of the paddle and boat, when the former is vertical, and $V - \cos x v$ the relative velocity of the paddle and boat, in a direction perpendicular to the motion of the former, when the paddle forms with the vertical the angle x ; and since the resistance is as the square of the relative velocity, the perpendicular resistance to the paddle in this position will be as $(V - \cos x v)^2$; and as this resistance is overcome with a velocity V , the whole effect of the paddle in this position is $(V - \cos x v)^2 V$.

But this resistance is perpendicular to the face of the paddle, and must therefore be resolved into two forces, one horizontal, which is wholly effective in propelling the boat, and the other vertical, which is wholly ineffective. This resolution gives

$$(V - \cos x v)^2 V \cos x = \text{effective force,}$$

$$(V - \cos x v)^2 V \sin x = \text{non-effective force;}$$

which, in the vertical position of the paddle, when $x = 0$, becomes

$$(V - v)^2 V = \text{effective force,}$$

$$0 = \text{non-effective force;}$$

because, in this case, $\sin x = 0$, and $\cos x = 1$.

To find the angle x when $(V - \cos x v)^2 V \cos x = a$ maximum, we have only to make its differential equal to zero, whence

$$0 = -2V \cdot d(\cos x) (V - \cos x v) V \cos x + V d \cos x (V - \cos x v)^2 \quad \text{Machinery.}$$

which reduced gives $\cos x = \frac{V}{3v}$.

The angle, therefore, at which the effective force is a maximum, depends upon the relative velocity of the paddle and the boat.

$$\text{If } V = 3, v = 2, \text{ then } \cos x = \frac{3}{6}, \text{ or } x = 60^\circ.$$

$$\text{If } V = 4, v = 3, \text{ then } \cos x = \frac{4}{9}, \text{ or } x = 63^\circ 38'.$$

$$\text{If } V = 5, v = 4, \text{ then } \cos x = \frac{5}{12}, \text{ or } x = 65^\circ 23'.$$

And by substituting these values of cosine x in these three cases, it will be seen how much the effective power of the paddle in its best position exceeds its effect in the vertical position. Thus

$$\text{Case 1. } \begin{cases} \text{Force on vertical paddle} = 3 \\ \text{At the angle } x = 60^\circ \text{ ditto} = 6 \end{cases}$$

$$\text{Case 2. } \begin{cases} \text{Force on vertical paddle} = 4 \\ \text{At angle } x = 63^\circ 38' \text{ ditto} = 12.8 \end{cases}$$

$$\text{Case 3. } \begin{cases} \text{Force on vertical paddle} = 5 \\ \text{At angle } x = 65^\circ 23' \text{ ditto} = 23.1 \end{cases}$$

These angles, however, which give the maximum effect exceed those at which the paddle meets the water in most practical cases, although in deep laden vessels the wheel is sometimes so much immersed, that the paddles do actually meet the water when forming an angle of 60° with the vertical, as is the case with the Salamander in the preceding Table of experiments; but, in general, about one-fourth the extreme circumference of the wheel may be supposed to be immersed, and then of course the paddle meets the water when at an angle of 45° .

(282.) It is not easy to find the sum of all the actions of a paddle, while passing through the water, because, in the beginning of its action, it is not wholly immersed, and a similar defect takes place at its exit; so that properly we ought to find the sum of all its actions from its first immersion until it is wholly immersed, and then the sum of its actions when wholly immersed; but this is a degree of precision which the uncertain amount of immersion would hardly require in such a case as the present. Our object will, perhaps, be sufficiently attained by considering the paddle as wholly immersed at the angle of 40° , and then to compute its effect while passing through an angle of 80° , as if it were wholly immersed through this arc.

To effect this, and at the same time to find the amount of all the non-effective forces, we must find the sums of the two following differential expressions, viz.

$$\int (V - \cos x v)^2 V \cos x dx = \text{effective force,}$$

$$\text{and } \int (V - \cos x v)^2 V \sin x dx = \text{non-effective}$$

It is not necessary for us to pursue this subject; enough has been done to show that the vertical position of the paddle is that in which it is least effective, and that where a wheel is so constructed, as that all its paddles shall act vertically, it is necessary to make that paddle larger than in the usual wheel, or to make the wheel revolve with a greater relative velocity in respect to the vessel. But every unnecessary increase of velocity absorbs a proportional quantity of steam, which is lost in effect as a propelling power, and, therefore, although

To find the
mean ac-
tion.

Manufactures.

with such a paddle, there is no non-effective mechanical resistance, the increased velocity of the wheel absorbs a quantity of power equal to or closely approximating to that which is expended with the common wheel in overcoming the non-effective resistances to which the paddles are in this case exposed. It is true that the increased velocity may be obtained by enlarging the diameter of the wheel without increasing the speed of the piston, and therefore without a greater supply of steam; still, however, the fact remains the same, that with the same area of paddle and diameter of wheel, the constantly vertically acting paddle must revolve with greater velocity than the common wheel to propel the vessel with equal speed.

Proportional effective and non-effective resistance.

(283.) In order to compute what part of the power of an engine is employed in propelling the vessel, and what part is expended in urging the paddle through the water backward, we shall first endeavour to simplify the conception of the operation, by referring to the case of a boat when being rowed. Conceive a boat with a square end whose section is a , and an oar with a square flat section, or, which is the same, conceive the end of the oar, instead of having such a square face, to be placed in another boat equal to the former, and both free and floating in still water; then a force being applied to the oar, both boats will offer equal resistances, and being equal, both will take up equal velocities, and half the whole force will be employed in giving the two motions. But if the area of one boat be A , and the other a , the velocities they must take up to produce equal resistances will be inversely as the square root of A and a ; that is, the resistance being as the square of the velocity, we must have $A v^2 = a v'^2$.

But the resistance $A v^2$ being overcome with a velocity v , and $a v'^2$ with a velocity v' , the actual forces employed in the two cases will be as $A v^3 : a v'^3$, or as $v : v'$; because $A v^2 = a v'^2$. To determine all the circumstances, therefore, we have the following equation, P being taken to represent the power or pressure on the oar, and w its velocity, viz.

$$\begin{aligned} A v^2 &= a v'^2 \\ A v^3 + a v'^3 &= P w. \end{aligned}$$

But the velocity w is dependent on the sum of the velocities $v + v'$, according to the length of oar or lever within and beyond the boat: let this ratio be $1 : r$, then

$$w = \frac{1}{r} (v + v');$$

wherefore

$$\begin{aligned} A v^2 &= a v'^2 \\ A v^3 + a v'^3 &= \frac{P}{r} (v + v'). \end{aligned}$$

Or if we make $v + v' = V$, then $v' = V - v$, the above become

$$\begin{aligned} (V - v)^2 a &= V - v^2 A \\ (V - v)^3 a + v^3 A &= \frac{1}{r} V \cdot P. \end{aligned}$$

In this form the equations become applicable to the case of steam vessels; V being the velocity of the wheel at the point of pressure, or the velocity with which the paddle and boat are separated from each other, v the velocity of the boat, and $V - v$ the velocity of the paddle through the water; a the area of all the acting paddles, and A the area of a square section, which would at the same velocity offer the same resistance as the action of the vessel submerged in the water. P the pressure on the pistons of the engines, and

$$r = \frac{3.1416 \cdot \text{diam. wheel,}}{2 \cdot \text{stroke of piston.}}$$

Machinery

If the pressure P is stated in pounds, then the resistance must also be stated in pounds. In this case the resistance

on the paddle is $(V - v)^2 a \times \frac{62\frac{1}{2}}{4g}$, g being equal to $16\frac{1}{2}$, the force of gravity, and $62\frac{1}{2}$ the weight of a cubic foot of water in pounds, and, therefore, the actual equations then are

$$(V - v)^2 a = v^2 A,$$

as before, and

$$\frac{62\frac{1}{2}}{4g} (V - v)^2 a + \frac{62\frac{1}{2}}{4g} v^2 A = \frac{VP}{r};$$

consequently, since $(V - v)^2 a = v^2 A$, the power $\frac{VP}{r}$

is divided between the paddle and vessel, in the proportion of $V - v : v$. When, therefore, as is generally the case in the vertically acting paddles, $V : v :: 3 : 2$, one-third of the whole power of the engines is expended on the paddles; whereas, in the other cases, viz. the common wheels, only one-fourth or one-fifth is thus lost; but to this must of course be added the loss from non-effective action as expressed in the preceding equations, (Art. 281.) which latter will, from the nature of the equation, be proportionally more as the vessel is more deeply laden; and this result is perfectly consistent with those drawn from the experiments in the foregoing Tables.

(284.) We cannot pursue this subject further in this place, but the reader, who is desirous of entering fully into the investigation, is referred to a Paper *On the Laws which govern the Motion of Steam Vessels*, in the *Phil. Trans.* 1834, part ii. by P. W. Barlow; we can only here state the results of the author's investigation, viz.

1. That when the vessels are so laden that the wheel is but slightly immersed, there is little advantage in the vertically acting paddle.

2. In cases of deep immersion, it has considerable advantage over the common wheel, as at present constructed.

3. That in the common wheel, while the paddle passes the lower part of the arc, or when its position is vertical, it not only affords less resistance to the engine, but is less effective in propelling the vessel than in any part of its revolution.

4. That in the new wheel, the paddle, while passing the lower part of the arc, affords more resistance to the engine, and is more effective in propelling the vessel, than in any part of its revolution.

This property of the vertical paddle is a serious deduction from the value of the wheel; for in consequence of the total resistance to all the paddles being so much less than in the common wheel, much greater velocity is required to obtain the requisite pressure, which is attended with the consumption of an additional quantity of steam, and, in course, of a proportionate loss of power.

This loss of power is most sensible when the wheel is slightly immersed, as may be seen from the Table; whereas the lost power, from the oblique action of the common wheel, is then scarcely perceptible. When the vessel is more immersed, and the angle of inclination at which the paddle enters is greater, the proportion of

General laws of action.

large diameter, and the paddles too small, is very sensibly exhibited in the experiment on the Medea. Her engines have the same length of stroke as those of the Salamander, Phœnix, and Rhadamanthus, and the wheel is twenty-one feet in diameter to the centre of pressure, while those of latter vessels are not above eighteen feet five inches, or eighteen feet six inches. The consequence is a considerable loss of power, from the greater velocity of the wheel than of the ship, the whole power of the engine being brought out in both cases. This loss of power is, of course, still small, compared with that of the common wheel when deeply immersed, so that in the experiment at Sheerness, her superiority of speed is perfectly consistent with the preceding calculations; at the same time we have no hesitation in saying, that an increase of speed of half a mile per hour at least might be obtained by a smaller wheel and more surface of paddle board.

This view of the case is still further confirmed by experiments on the Monarch steam vessel. A former experiment on this vessel, not reported in the Table, with a wheel of less diameter and larger floats, gave a speed above eleven miles per hour. In the experiment given in the Table, the average velocity is 10.8, so that a sensible diminution of speed was produced by enlarging the diameter of the wheel.

(285.) *Proportions and Dimensions of several English Steamers.*

The following list of the proportions of steam vessels, their tonnage, powers, dimensions of cylinders, length of stroke, and other particulars, will illustrate the practice of some of the best engineers, and the several proportions adopted by them. We give also the following particulars of the American steamer, the De Wit Clinton, by which it will be seen how much our Transatlantic brethren exceed us in the dimensions of their vessels, and in the power of their engines.

De Wit Clinton Steamer.

Passage from New York to Albany, 150 miles in 9 hours 18 minutes; upper deck 233 feet; best cabin 175 feet; breadth water line 28 feet; draws 4 feet 6 inches water; 66 inch cylinder, double stroke 10 feet; 4 circular valves, $17\frac{1}{2}$ inches diam.; diam. paddle wheel 22 feet; wide 15 feet; depth not given; 37 floats; 26 strokes per minute; 4 iron boilers, one fore and one abaft of each wheel; 4 chimneys; steam 20 pounds on safety valve; expanded inch cylinder 10 pounds average; estimated pressure 12 pounds, deducting all friction; 646 horse power; shaft $14\frac{1}{2}$ inches wrought iron.

W. & A. G. Maudslay, Son, and Field, London.

8. That an advantage would be derived from a wheel of large diameter, so far as the immersion of the paddle produced by loading the vessel would not so sensibly affect the angle of inclination of the paddle ; this, however, cannot be attained advantageously with an engine of the same length of stroke, because to allow it to make its full number of strokes with the large wheel, the size of the paddles must be diminished, which is a much greater evil than a wheel of small diameter with larger paddles. To have larger wheels, it is therefore either necessary to have the engines made with longer strokes, or to have the paddle wheel on a different shaft to the engine, in order to diminish their speed. These are both practical inconveniences in sea boats, and we must therefore consider the wheels to have gained their greatest limit in point of diameter. For the navigation of rivers, as the construction of the boats will admit of much greater speed given to them than is at present attained, larger wheels may be employed.

The ill effect resulting from making the wheel of too

Description of a Boat Engine of the usual form, and with a Vibrating Cylinder.

Pl. xix.
and xx.
Boat engine
described.

(286.) Plate xix. fig. 1 and 3, and pl. xx. fig. 2, are the plan and sections of his Majesty's steam ship *Phœnix*, of 820 tons burden, with two engines of 110 horse power each, by Maudslay. A A is the keel of the vessel, B B the main timbers, and C C the upper deck. In the part occupied by the engine and boiler, the vessel is clear from the upper deck down to the hold. Four timbers of great strength, D D D D, extend in a longitudinal direction from one end to the other, which support the engine and boiler. The great strength of these beams is of importance, in order to distribute the strain produced by the reaction of the engine over as great a surface as possible. In the *Phœnix* the engine is placed with the cylinder E E towards the head of the vessel; this arrangement has, however, been altered in the *Medea*, which has been since built, the engines being placed with their cylinders to face the boiler or stern of the vessel. This has the effect of throwing the main shaft of the paddle wheels more forward, which is considered an advantage. F F are the boilers, of which there are four, placed together in such a manner that any number may be used as required. Three is the greatest number required when a vessel is using its full quantity of steam; one being always ready for use in case any accident happens. The fire-places are now generally placed at the forward part of the boilers, as shown at *a a*. In some of his Majesty's vessels they have been placed in the after part of the boiler; or rather the boilers have been reversed, with a view of bringing the fire-places as near as possible to the coals contained in the coal boxes G G G, in order to avoid the labour of bringing them the length of the boiler: but this arrangement has not been found to answer in consequence of the want of air, which results from such a confined situation. In some vessels one half of the boiler has been turned one way and one half the other. This practice has also been discontinued, and they are all now used as shown in the plate.

The construction of the boilers is varied in vessels of different dimensions; sometimes they are made square, as shown in the drawing, sometimes to fit the shape of the vessel, or cylindrical. The fire circulates through flues which pass several times from one end of the boiler to the other, in order that as much heat as possible may be given out before the flame and smoke arrive at the chimney H H. The part marked I is a reservoir of steam, from which the steam is conveyed to the cylinder by the steam pipe S S. K K is the waste pipe through which the steam passes off from the safety valve.

The engine needs but little description, as it only varies from the low pressure engine used on land in the arrangement of the parts, to the circumstances in which it is placed. Each engine has two beams, *b b*, situated below the cylinder, one on each side, which are attached by side rods to a cross head on the piston rod. The parallel motion is effected by horizontal rods *c c*, attached at one end to a joint in the side rods of the beams, and at the other to a small crank, which, by its rotation, allows the deviation from the straight line which must occur to preserve the motion parallel. The other extremity of the beams are connected by a cross piece to which the crank rod is attached. The crank in

boat engines is generally a little varied from those used on shore in consequence of the sudden blow it is liable to from a sea striking the wheel, which would endanger breaking them off if they were connected by one pin passing through both. An intervening piece is, in consequence, introduced, termed the driving link, shown at *e*, fig. 2, which not only preserves the crank, but takes off the shock from the engine. Sometimes a drag link is used, which only differs from the above by being placed on the contrary side of the engine crank, so that it drags the other after it instead of driving it. The air pump is seen at *f*; it is worked by a cross head, with side rods connected to the beam; *d* is the slide valve which receives its motion from the eccentric *g* on the main shaft; *h* is the condenser, and *k* a cylindrical vessel which forms the hot well; its height being required to prevent the motion of the vessel from dispersing the water. In order to avoid confusion in the drawing, two parts of the engine have been omitted which it is necessary to mention, *viz.* the pump which supplies the boiler with water and the bilge pump; they are placed one on each side of the cross head of the air pump, so that their bucket rods work through a projected part of it, and can be put in gear when required by a screw in the cross head.

P P P is the paddle wheel; it has two bearings, one in the side of the vessel, and the other in the paddle box; *l l l* are small cast iron flanches or wheels attached to the shaft wheel, having mortises left in them to receive the wrought iron arms *m m m*, &c. These arms are further secured by flat wrought iron rings which are bolted to their extremities; and in the larger description of wheels, such as the present, an additional one, at about two-thirds of their length, is added. The arms of the wheel are generally made to radiate from the centre. In some wheels latterly constructed by Maudslay, they are, however, made to radiate from points at a little distance from the centre. This is done with the view of diminishing the angle with which they enter the water, in order to take off the shock from the engine, produced by the paddle floats striking the water at too obtuse an angle. The paddle boards are made of planking of about two inches in thickness, which are bolted to the arms by bolts, one end of which is provided with a hook which fits over the wrought iron arm, and the other passes through the board, and has two nuts, one above the other, which are found necessary from the great tendency they have to become loose from the jarring of the board.

Within a few years a paddle wheel upon a new principle has been applied to several Government vessels, termed Morgan's wheel. The object attained by it is to cause the paddles to enter the water in a position nearly vertical, instead of at an angle. This is found to prevent the injurious shock which is given to the engine by the floats of the common wheel, particularly when much immersed, and is also found in such cases to add to the speed of the vessel. A paddle whose action is always vertical, has long been considered desirable, and the inventions to effect this object have been very numerous, but have been generally so complicated, and attended with so much friction and liability to get out of order, that they have never been brought into general use. These wheels are certainly the most simple of the kind, but they are still attended with a liability to derangement, and consequent expense in repair, which materially affects their value.

Manufac-
tures.
Pl. xx.
Fig. 4.

Fig. 4, p. xx. represents the mechanism of the wheel; *aaaa*, &c. are the paddles which turn upon spindles, having a bearing in the angles of the framework of the wheel *b, b, b*, and which is of a polygonal figure, with as many sides as it is required to have paddles. The inside frame or polygon is alone attached to the shaft of the engine, which does not continue beyond the side of the vessel; and the outer one has an independent bearing on a centre attached to the paddle box, so that it receives its motion entirely from the rim or angles of the polygon; by this means the space between the sides of the wheel is left entirely free. The part marked B is a part of the shaft or centre upon which the outer side of the wheel revolves, projected in an inclined direction to the middle between the sides, but of course to a point considerably eccentric with the wheel.

Each paddle has a crank *c*, attached to it at an angle of nearly ninety degrees, and rods *d d d*, &c. connect the extremity of this crank with a movable boss which revolves upon the fixed point B.

It will thus be seen, that in consequence of the point B being situated out of the centre, the paddle will assume different positions during the revolution of the wheel, which positions can be so arranged as to differ very little from a vertical direction while passing the lower part of the revolution, or that part where the action of the paddle takes place.

This will sufficiently illustrate the principle of the action of the wheel. In the construction a variety of practical considerations, of course, require to be attended to, one of which it is, perhaps, necessary to mention, *viz.* that the piece B, to which the rods are attached, has motion given to it, otherwise they would not keep at their proper distances. This is effected by securing one of the rods, which is made stronger than the rest, firmly to the piece B. In this way the paddle, while its position is changed by the fixed rod or driving arm, gives it a rotation round the fixed point, and with it all the remaining movable rods of the wheel.

Maudslay's
vibrating
engine.
Fig. 5

(287.) *Maudslay's vibrating engine.*—Among the late improvements in steam boats may be mentioned the introduction of the vibrating engine by Maudslay, by means of which a saving of weight and expense of Machinery is effected, and at the same time a considerable space in the vessel is saved by its taking up less room than the beam engine.

Fig. 5 is an elevation of Maudslay's vibrating engine, which differs from those previously constructed, simply in the application of the slide valve, for which he has within a few years taken out a patent. A A A is strong cast iron framework which supports the hollow cylindrical axle in proper brasses at B, and the main shaft of the engine at its upper part. C C C is the cylinder, which is surrounded at D D by a hollow belt, one end of which is connected to the opposite hollow axle of the engine, and to the top and bottom of the cylinder, by means of flat pipes seen at F F. The slide valve C C is bolted to the cylinder between these pipes: it has two flanches upon it, *aa, bb*, which serve as a guide for the rods which give motion to the slide; the part of the slide valve casing marked *cc* is made smaller, in order to be able to get at the packing of the lower valve, which is effected by taking off the flanch *dd*. The manner in which motion is given to the slide will be sufficiently understood by the drawing, and, therefore, needs no further description. The interior construction of the valve and cylinder exactly resembles that of the

land engine. The action of the engine is as follows. Machinery. When making the down stroke, the steam enters the top of the cylinder by the hollow axle H and slide valve, while the bottom of the cylinder is open to the condenser by the flat pipes and hollow belt; the connection is of course reversed when the piston arrives at the bottom of the stroke.

When double engines are employed, as is usual in steam vessels, one air pump and condenser are placed between the two cylinders, the air pump being worked by the crank shaft which connects the two engines.

Several engines of this description have been fitted to small steam boats, and have been found to answer perfectly well; they have not, however, been at present used in the larger description of vessels.

Application of the Steam Engine to Inland Communication.

(288.) The inland traffic between different parts of a Country is of so much national importance, that it will be proper in treating of the locomotive engine, to take a general view of the progress which has been made in a comparatively short period in England in all her internal communications, to show also how much her greatness has increased, and how much it is dependent on facility of transport. With roads nearly impassable, she remained for many years a comparatively poor and feeble nation; the corn grown in one district could not be transferred to another without such an enormous expense of carriage as to act nearly as a prohibition. On the other hand, the transfer of raw materials served to raise the price of every kind of Manufactures, which were again subject to an additional expense if carried to the distance of some miles from the towns in which the goods were made: thus while one County could have supplied food to another, which would gladly have exchanged for it the cloth of its manufacture, as much wanted by the former as the corn by the latter, neither could assist the other in consequence of the almost insuperable obstacle opposed to conveyance. It is true that, being an island, surrounded on every side with seas and navigable channels, a communication was easily kept up along her coasts; and to this circumstance, in the early period of her rise, there is no doubt England was largely indebted for the comforts she then enjoyed. Some navigable rivers also extended these benefits inland to certain distances and to certain points, which points, however, for want of road conveyance, remained nearly isolated from each other; so much so, that weights, measures, and nearly every standard of comparison, were different in different Counties.

Such, we may say, was the state of England in the commencement of the XVIIIth Century: at that time the formation of turnpike roads began to be a favourite measure, both with the People and the Government; but the progress was slow, and so late as the middle of the last century, to travel more than forty miles a day was considered amongst the wonders of the time. The inhabitants of a County-town or city, at a distance of a hundred miles from London, seldom thought of any established conveyance by coach or otherwise to perform the journey in less than two days and two nights; indeed, the writer of this Essay remembers when the quickest conveyance between a large town, only a few more than one hundred miles from London, was the work of two long days and one night, a journey which is now performed regularly

Introductory remarks.

State of the English roads in 1700.

Manufac-
tures.

in twelve hours, and has been done in ten and a half, and which will, perhaps, soon be effected in much less time.

Such has been the effect of turnpike roads, of which we had in 1821, according to the Parliamentary Report, 24,531 miles spread over the Country, in different parts of England, Wales, and Scotland. Of these, 18,320 miles are in England, 2591 in Wales, and 3611 in Scotland.

Canal com-
munication.

(289.) Some years before the period last alluded to, a new stimulus had been given to inland communication, first by the establishment of the Mersey and Irwell Company, and secondly by the formation of the first British Canal by the Duke of Bridgewater, who, in 1758, obtained an Act of Parliament and set aside large sums to the prosecution of inland navigation, by which he not only realized a princely fortune, but may be said to have laid the foundation of his Country's commercial greatness. The advantage of Canal navigation at that time was enormous. On our best roads at that day the force of traction was certainly not less than one-eighth or tenth of the load and carriage, and when these were heavy the speed could not exceed two miles or two and a half miles per hour; whereas on a canal, the force of traction at that pace is not above a thousandth, or at the most one-nine-hundredth of the load. Here at once the force of traction was reduced to one-hundredth part of its original amount, and of course with advantage to places lying within the range of the Canal. An advantage so striking could not but be seized with eagerness by persons of foresight and fortune; and accordingly, in a few years after we find Great Britain penetrated with Canals in every direction, circulating and connecting her various points of product and consumption, distributing animation, conveniences, and luxuries through her extended surface, and, like the veins of the human body, giving health and vigour to the whole system.

(290.) Some idea of the immense increase of Manufactures which followed the above two early attempts at inland water communication, may be gathered from the following details, given by Mr. Booth in his Official Report relating to the Liverpool and Manchester Railway. In 1760, 2560 vessels paid dock duties at Liverpool; in 1824, 10,000; and in 1829, 11,383:—in 1760, the population of Liverpool was 26,000; in 1824, 135,000; the population of Manchester being, in 1760, 22,000, in 1824, 135,000:—in 1784, only eight bags of cotton were imported into Liverpool from America; in 1824, 409,670 bags; and in 1829, 640,998. In 1790, the first steam engine was set up in Manchester; in 1824, there were 200 steam engines there: in 1814, there was not one power loom in Manchester; in 1824, there were 30,000. In 1824, the average quantity of raw and manufactured goods transmitted between the two towns was 1000 tons daily, and it now amounts to 1300 tons; about 1000 of which pass from Liverpool to Manchester, and 300 from Manchester to Liverpool. The bulk of this immense traffic was carried by means of the two Canals before mentioned.

Even with these accommodations, goods had to be first sent up the River Mersey to Runcorn, a distance of about twenty miles, and thence by one of the two canals to Manchester, making the whole distance between the two towns about fifty miles. In Summer time there was frequently a deficiency of water, obliging boats to go only half loaded, while in Winter they were sometimes locked up with frosts for weeks together. Vessels, too, were often arrested in their progress up the Mersey

by contrary winds, and exposed to loss and damage Machinery. from tempestuous weather. The average length of the passage was thirty-six hours; but owing to the various causes of delay just enumerated, there have been instances of goods being a longer time on the way (by water) from Liverpool to Manchester than from New York to Liverpool!

The present length of Canal navigation, in England, Scotland, and Ireland, exceeds three thousand miles, which, ramifying in all directions from coast to coast, and penetrating our most inland districts, gives a facility of conveyance of every kind of material, wrought or unwrought, scarcely to be comprehended by those who have not paid particular attention to the subject. The barges in one place export corn and bring back manure; in another, lime, iron ore, and coals, and return with the iron manufactured into articles for home use and for exportation; while in a third, they transfer the raw cotton received from abroad, and return with manufactured cotton goods ready to supply every market in the World; and this with so little labour, that in one case, falling within the knowledge of the writer, a load of twenty-one tons in a boat of six tons, was drawn by a man and a young girl his daughter, at the rate of 1.9 mile per hour through the usual passage; the horse, which commonly did the work at a somewhat greater speed, being unable from accident to perform his usual duty.

As far as regards the mere force of traction, indeed, no means of conveyance for heavy goods can ever come in competition with Canals at a slow pace; but as Manufactures and Commerce increase, time becomes more valuable; speed is essential to every transaction; the mere charge of conveyance is of less consequence than the time of transfer, and hence the idea of Railways, which, indeed, seem in some few instances to have preceded the Canal; but they were constructed of wood, and were of course very imperfect.

(291.) The first wooden Railway seems to have been employed at Newcastle, in 1680, for transporting coals from the pits to the river Tyne, upon which duty, even at that time, there were employed from four hundred to five hundred carts; hence it became of course an object of manifest importance to reduce the great expense thereby incurred in the keeping up of horses, drivers, and roads; and the plan of wooden rails was the best, and, indeed, the only effectual method which could at that time have been devised for the purpose; for which also the situation was in other respects favourable, presenting in most cases an easy descent towards the river. These Railways were then very generally introduced, and continued for a long period in use in this part of the Kingdom. Slips of ground of the requisite breadth for the Railway were marked out between the coal pits and the river, and were either leased by the coal owners or purchased of the different proprietors whose ground the proposed line of road intersected in its course. To obtain the most easy and regular descent, this line was varied in its direction to meet the inequalities of the ground; or, where these inequalities were inconsiderable, it was carried straight forward, and the regular slope made by embankments and cutting. The ground being then smoothed and levelled, as for an ordinary road, large logs of wood, termed *sleepers* cut in lengths equal to the breadth of the road, were laid across it, and firmly bedded into it at short distances, to sustain and hold fast the rails or slips of wood on

Wooden
Railways.

Manufac-
tures.

which the waggon wheels were intended to run. These rails were made of beech, and were laid end to end, so as to form two continued lines of rails or wooden ridges, running parallel to each other along each side of the road, crossing the large logs at each of their extremities, on which they rested as on so many foundations; and were also nailed, or otherwise secured, to keep each piece in its proper place. The waggons were of the usual construction, but of a large size, so as to contain several tons of coals, and set upon low wheels, the smoothness of the way rendering wheels of the ordinary size unnecessary. On these rails a single horse could readily draw three tons of coal from the pits to the river. Where any steep declivity occurred on the road, this was termed a *run*, or an inclined plane; and on it the descent of the waggons was retarded, and regulated by a species of brake, or crooked lever, termed a *convoy*, attached to the waggon, and managed by the driver. The banks of the Tyne, near Newcastle, are remarkably steep on each side; but instead of forming inclined planes on them, the Railway was here continued on a wooden stage, raised to the same height as the top bank of the river, and carried forward until it came perpendicularly over the river side, where a wooden platform, termed a *staith*, was erected for the convenience of delivering the coals: the waggons being emptied into a trough or spout, down which the coals descended either directly into the ships, or into the store below.

Iron Rail-
ways.

(292.) *Of iron rails.*—Such was the construction of the original rail, in which is evidently perceived all the parts and members of the Railway, as it is formed at the present day; viz. the regular formed road, the rails, the sleepers, the low waggons, and the inclined plane. Their only defect consisted in the soft and decaying nature of the wood, the wear and tear of which caused so much expense for repairs as greatly limited their application; so that it was only the shortness of the distance, and the great extent of the traffic, which rendered their application at all beneficial. It was not till about the year 1738 that they were attempted in the collieries of Whitehaven; and it does not appear that they were adopted in any other part of the Kingdom. The use of iron, therefore, in the place of wood, was an essential improvement in the construction of Railways, and caused, indeed, a complete change in this, as it has done in every other branch of practical Mechanics into which it has been introduced. Flat bars of iron were at first fastened on the top of the wooden rails; but after various unsuccessful attempts, the rails themselves were at last wholly composed of iron, cast in short bars, united at their extremities, and resting on sleepers, or square blocks of stone, disposed at short distances along each side of the road; and this construction having been once fairly reduced to practice, was not only adopted universally in the place of wood, but soon led to new and more extensive applications. Iron Railways were quickly introduced into all the coal and mining districts of the Kingdom. They were employed on Canals, in place of locks, to raise the barges on an inclined plane from a lower to a higher level; in some instances they were adopted in preference to the Canal itself; and on the whole, forming an important auxiliary to inland navigation, pushing the channels of trade and intercourse into districts otherwise inaccessible, and even into the interior of the mines; and to so great an extent is this now carried, that, according to the Report of M. Dupin, the celebrated English voyager, the under-ground Railways alone in

Newcastle, and its immediate vicinity, exceed in length one hundred and fifty miles.

(293.) *Locomotive engines.*—Railways were thus carried to a great extent, but the transfer of the loads was made by the assistance of horses; one of these animals on a well-constructed iron rail would do more work than six horses on a common road, or, if necessary, instead of making him draw more, his speed might be increased: still, however, we were dependent on the horse, and the only use made of the Railway, till within a very few years, was the transfer of goods, or of various materials from one place to another, and great speed was neither attempted nor thought desirable. A very few years, however, has introduced an extraordinary change. Railways and locomotive engines are seldom now separated in imagination. With the horse we were limited in speed, however light his load he could not move with more than a certain velocity; but the locomotive engine is not thus circumscribed. Journeys have now been actually performed at a rate of motion far exceeding any thing that could have been contemplated some years ago; thirty-five miles per hour have been effected, twenty and twenty-five miles is the common pace, and to what further extent a practice, only yet in its infancy, may arrive, it is impossible to foresee.

Another step is still in progress. Hitherto, whether horse or locomotive engine has been employed, a Railway has been thought essential for the performance, and consequently this means of transfer could be procured only in particular lines of road, where there was sufficient traffic to answer the charge of a first great outlay; this drawback on general convenience has led to an endeavour to substitute locomotive carriages on common roads, or on roads rather exceeding in their state of perfection the common road, but without rails. Some journeys have been made with more or less success, but upon the whole, with so much as has led to the formation of a Company for establishing this mode of travelling, and there seems every probability that a few years will cover our roads with carriages of this description. Of course the power necessary to be employed in this case will be much greater than on a Railway; but the very general range which such carriages may take is so great, that it must be the wish of every one to see these well-intended efforts directed to a successful termination.

Having thus taken a general sketch of the progress of inland communications in Great Britain, we shall now enter a little more into detail, by examining the actual force of traction in the different modes of conveyance according to the results of the best experiments, the construction of different kinds of Railways, and a description of those locomotive carriages which have hitherto been most approved, either for Railway or for common roads.

Comparisons of the Force of Traction on Common Roads, Canals, and Railways.

(294.) *Common roads.*—There is necessarily great uncertainty in deductions formed from experiments made for the purpose of determining the force of traction on common roads; but the following, reported by Mr. Telford to the Society of Civil Engineers, made on different slopes, are amongst the best we can select, although there are discrepancies in these which are not easily to be explained.

1 in 600	10	128	33.59
horizontal.	10	?	32.93

There are some anomalies in these results. First, it appears that a much greater force is necessary to move ten miles an hour than six, which is at variance with theory; for the force of resistance being balanced in both cases, there ought not be any difference in the force of traction, unless the resistance of the air should operate to this amount. In the next place, the forces at different slopes are not consistent; a change of slope from 1 in 20 to 1 in 30 seems to make a difference of 103 pounds, while the difference between 1 in 30 and 1 in 40, makes only a difference of 5 pounds. The traction on the level road is not given, but deducing it from the slope of 1 in 600, it would appear to be about 107 pounds, which is more than a twentieth of the load. It is, however, we believe, generally considered to be on a good turnpike road about one-thirtieth; it is so stated in Leslie's *Nat. Phil.*

The following results are also given on Mr. Telford's authority:—

1. On well made pavement, the draught (of each horse) in a waggon weighing about 21 hundred weight is thirty-three pounds.

2. On a broken stone surface or old flint road, sixty-five.

3. On a broken stone surface upon a bottom of concrete, formed of Parker's cement and gravel, forty-six.

4. On a broken stone road upon a rough pavement foundation, forty-six.

(295.) *Resistance on a Canal.*—On a road, the resistance is the same at all speeds, but in a Canal this is by no means the case. The common law of the resistance of fluids makes the resistance increase as the square of the velocity, but this does not hold good in Canals. From many experiments made by the writer on the Grand Junction and on the Birmingham Canals, there is no doubt the resistance varies very nearly as the cube of the velocity. This may, and probably does in part proceed from the water being confined by the sides of the Canal; moreover, the water always rises in front of the bow of the vessel, while a corresponding vacuity occurs at the stern, and this inequality is greater as the velocity is greater, whereas the theory supposes that every particle of water, as soon as it is struck, escapes and offers no further impediment; but from whatever source it arises, there can be no doubt that the resistance to a body in motion in a Canal varies very nearly as the cube of the velocity.

The manner in which the experiments above referred to, and of which the results are given below, were made, was by passing a rope over a pulley fixed to the regular towing post in the barge, which carried a basket containing different weights. This rope, which was smaller than the towing rope, was attached to the latter, which was taken on shore for hauling along the boat or barge, either by men or horse as stated below. After the motion had commenced and acquired the requisite uniformity, the amount of weight in the basket was adjusted by either adding or taking away some till the basket just sustained itself between the deck and pulley; and this weight, including that of the basket, &c., was considered the force of traction. Marks were previously made along the bank, at a chain's length distance from each other; a person was also present with a stop-watch, and when the motion had become uniform and the basket properly suspended, a sign was given to look out for the next mark; as the boat passed this, the time was noted, and again at the end of the distance, which varied in different experiments from thirty, forty, or more chains: by this means the velocity of the barge was very accurately determined. The estimated weight of the barge and the exact amount of the load were carefully registered, and the results of the experiments were as stated below, with some others made precisely in a similar way in the river Mersey, and one or two other places at which the writer was not present.

Law of resistance.

(296.) In order to arrive at a law of resistance as depending on velocity, it will be best to select for comparison those made in the same Canal, or in Canals of the same breadth; because, as we have already stated, it is not improbable that the law is in some measure influenced by the degree of facility with which the water can escape, or the want of that facility, which is of course greatest in the narrow Canal.

To arrive at this law let V, v represent two different velocities, and F, f the corresponding forces of traction; then supposing F to vary as some power of V , let m denote the index of that power, so that

$$V^m : v^m :: F : f;$$

$$\text{then } f V^m = F v^m$$

$$m \log V + \log f = m \log v + \log F.$$

$$\text{Whence } m = \frac{\log F - \log f}{\log V - \log v}$$

Now making this calculation for the different cases, we find from the Ellesmere boats 2 and 3 $m = 3.08$
 Ditto 3 and 4 $m = 2.60$
 Ditto 4 and 5 $m = 2.73$
 Grand Junction $m = 3.00$

$$\frac{4}{11.41}$$

$$2.85$$

which is nearly as the cubes; and the same appears to be the general character of the results, whether on light or heavy barges. It is useless, therefore, in the face of such experiments, to say that theory requires the power to be as the square. We have already stated a probable cause of the discrepancy, and whether that be sufficient or not, the fact is still the same; and we must proceed in our comparison with the results given by experiment,

and which are such as to prove the entire inutility of attempting to bring Canals to compete with Railways so far as speed is concerned; although some attempts of this kind have lately been made, wherein it is maintained that notwithstanding this law may be true in moderate velocities, an entirely different law has place with great velocities; that with these the boat will rise up on the wave which we have mentioned as impeding its velocity, and skim along its surface with a diminished instead of an increased resistance.

We are much afraid, however, that the increased resistance attending at least all common velocities, will always be an impediment to rapid canal transfer; and that the proprietors of these works must be content to proceed at their usual pace of two or two and a half miles per hour, at which rate no other means of conveyance can ever come in competition with them in regard to economy, notwithstanding the first outlay for such works is necessarily very great.

(297.) *Resistance on a Railway.*—The following results are collected from different Works, and all are resting on the best authorities.

- Ratio.
1. Mr. Silvester states that in empty waggons 23 $\frac{1}{2}$ hundred weight, the weight of the waggon itself, is moved along by a force of 14 pounds $\frac{1}{18}$
 2. On the same authority it appears that 50 pounds will overcome the friction and resistance of a loaded waggon on the same rail, weighing together with its load 76.25 hundred weight $\frac{1}{17}$
 3. Mr. Wood states that 50 pounds will draw along a horizontal rail a loaded waggon of 80 hundred weight $\frac{1}{17}$

Resistance on Railways.

Manufac-
tures.

4. Mr. Greenshaw says that 10 pounds will overcome the friction of an empty waggon weighing 2576 pounds on a horizontal rail. $\frac{1}{257}$
5. And that 50 pounds will draw along a like plane a loaded waggon of 8512 pounds. $\frac{1}{170}$
6. In another experiment resting on the same authority, it appears that on a rail whose inclination is $\frac{1}{180}$, the waggon will just descend without acceleration. $\frac{1}{180}$
7. And that in common practice 14 pounds will draw 23 hundred weight. $\frac{1}{184}$
8. And again, that on a rail whose inclination was $\frac{1}{9}$ of an inch to a yard, or $\frac{1}{32}$, the power necessary to draw down the loaded waggon of 8512 pounds, is equal to the drawing up the empty waggon of 2576 pounds; this gives. $\frac{1}{170}$
9. Mr. Jessop states that the best horizontal rail gives. $\frac{1}{200}$
10. But common practice not more than. $\frac{1}{150}$
11. Mr. Palmer reports that on an inclined plane at $\frac{1}{90}$, an empty waggon of 3666 pounds required a force of 5 pounds to prevent its descending. $\frac{1}{67}$
2. And that on an inclined rail of $\frac{1}{30}$, the same waggon required 108 pounds to prevent its descent. $\frac{1}{74}$

See the Works of the several authors above quoted on railways.

These experiments all tend to one result, which is important, viz. that the resistance increases faster than the weight; or that the greater the load the greater is the proportional power of traction: this is supposed to arise from the heavier loads bending in a slight degree the rail as it passes over it, whereby the effect is always equivalent to ascending a slightly inclined plane.

The usual Railway waggons are made to run on low wheels; if others of greater diameter were employed, there is no doubt both friction and resistance would be proportionally reduced.

(298.) From these results, and those before given on Canals, it is clear, that although with low velocities the force of traction is much less on Canals than on Railways, yet with a little increased velocity, the two become equal; after which the advantages are altogether in favour of the latter. It appears from the preceding Canal experiments, taking one on which the velocity is exactly $2\frac{1}{2}$ miles per hour, and its force of traction $\frac{1}{689}$ of the whole load; let it be required to find the velocity when the resistance shall be $\frac{1}{180}$, that is equal to the resistance on a good Railway; here

$$\frac{1}{689} : 2\frac{1}{2}^3 :: \frac{1}{180} : v^3,$$

or

$$v = \sqrt[3]{\frac{689}{180} \times 2\frac{1}{2}} = 3.91.$$

At a velocity, therefore, of about four miles per hour, the Canal and Railway give equal resistances; but at double that velocity, that is, at eight miles per hour, the advantages are eight to one in favour of the Railway. Supposing, as we have all along done, that the rail is perfectly horizontal, and abstracting from the resistance of the air, which is not considerable till the velocity becomes more than is here stated.

(299.) *Inclined rail.*—When a rail is inclined, and the carriage is either ascending or descending, the nature of the resistance is modified in two ways; first, gravity

Ratio.

has now its influence, and either tends to accelerate or retard the motion, according to the direction in which the carriage is moving, accelerating it in its descent, and retarding it in its ascent; and this effect, from the known laws of bodies on inclined planes, varies as the sine of the plane's inclination. Hence if the whole weight of the carriage and load be W , this effect will be expressed by $\pm W \sin a$; a being the inclination of the plane. Again, the pressure on the plane varies as the cosine of the angle; hence the friction and resistance being proportional, if $\frac{W}{m}$ denotes the friction on a hori-

zontal plane, $\frac{W}{m} \cos a$ will be the same on a plane whose angle of inclination is a . Whence again the whole resistance, abstracting still from that of the air, is expressed by

$$\text{Resist.} = \frac{W}{m} \cos a \pm W \sin a;$$

the upper sign having place when the carriage is ascending, and the lower when it is descending: therefore, in the latter case, when $\cos a = m \sin a$, the carriage will be in equilibrio on the plane; when $\cos a$ is greater than $m \sin a$, some force equal to the difference is necessary to sustain the carriage; but when $\cos a$ is less than $m \sin a$, the carriage will descend by the effect of gravity, unless some counteracting force be applied to check its motion.

In short rails, which are loaded only one way, the inclined plane presents great advantages, supposing the load, as very commonly happens, is to descend; for in this case the slope of the rail, or the proportion between the weight of the empty and loaded carriage may be so adjusted to each other, that the acceleration of the descending load shall just balance the retardation of the ascending waggon, or just so far exceed it as to produce the requisite degree of velocity in both.

Suppose, for example, the weight of the loaded waggon to be W , and that of the empty waggon w , then by the foregoing formula

$$W \sin a - \frac{w}{m} \cos a = \text{force of descending load};$$

$$w \sin a + \frac{w}{m} \cos a = \begin{cases} \text{retarding force of ascend-} \\ \text{ing empty waggon.} \end{cases}$$

Whence, when both are equal,

$$(m \sin a - \cos a) W = (m \sin a + \cos a) w;$$

therefore

$$\frac{W}{w} = \frac{m \sin a + \cos a}{m \sin a - \cos a};$$

from which expression the ratio of W to w is readily determined when the angle is given.

When the load is given, and the weight of the waggon required, then calling

$$\frac{W}{w} = r, \sin a = x, \cos a = y,$$

$$\frac{m x + y}{m x - y} = r,$$

$$m x + y = m r x + r y,$$

$$(r + 1) y = (m r - m) x;$$

or
whence

$$\frac{x}{y} = \frac{r + 1}{m(r - 1)} = \frac{\sin a}{\cos a};$$

and the ratio of the sine to cosine being thus determined, the angle itself will be readily obtained.

Machinery.

Resistance
on Canals
and Rail-
ways com-
pared.

Inclined
Railway.

Manufac-
tures.

Such questions as the above, however, only occur in particular cases; the great question of the economy of Railways, for general communication, is by supposing that the rails can be made horizontal, or so nearly so, that the accelerating force of gravity shall not exceed the resistance arising from friction and the usual retarding forces.

Action of
locomotive
engines on
railways.

(300.) In estimating the effect of locomotive engines on a Railway, it will be found that the force required is the same as if the centre of the wheel were fixed, and the resistance to the motion acted at the circumference of the wheel.

Pl. xxi.
Fig. 8.

Let C D, fig. 8, pl. xxi. represent the axles of the fore and hind wheels of a locomotive engine, which rest on a rail at the points A and B; and let a force act from some point of the carriage by the rod G F, upon the crank C F, which turns with the wheel C A round the axle C. The rod exerts a certain action on the crank at F, and an equal reaction on the carriage at G. If F G meet C A and D B, in H and E, the action on the wheel C A may be supposed to take place at H, and the reaction upon the carriage at E. Join C E, and draw H K parallel to C E, and let the equal action and reaction in the line G F or E H be represented by E H and H E.

The force E H is equivalent to K H, C H, of which the latter is supported and destroyed at A; the former is effective on the wheel C A.

The force H E is equivalent to K E, C E, of which the former diminishes the pressure at B, the latter draws C towards E.

Therefore the wheel C A is acted upon by two forces, K H, C E; which tend to turn it about A. Also the resistance which the carriage experiences to its motion in the direction C D may be considered as a force acting at C, perpendicular to C A. Let R be this force, and let A N M be perpendicular to C E, H K. Then the forces and the resistance must balance each other, and by the property of the lever, if S be the force K H, or C E,

$$R \times CA + S \times AN = S \times AM;$$

or $R \times CA = S \times MN.$

Let C O be drawn perpendicular from C upon E H, and H I upon C E; and let P be the pressure exerted by the rod G F; we then have

$$P : S :: EH : EC :: HI : CO :: MN : CO;$$

therefore

$$P \times CO = S \times MN;$$

and

$$R \times CA = P \times CO.$$

Hence the effect is the same as if C and the force P acted by means of the rod G F and crank C F to produce motion in the wheel, in opposition to a force R acting at the circumference.

In order that the engine may be urged in the direction C D, the force which acts by means of the rod G F must be a pushing force, while the line G F falls below C, and a pulling force when this line falls above C. If G be connected with the piston of a steam engine, these two parts of the motion must correspond to the up and down stroke, or the backwards and forwards stroke.—Whewell, *Mechanics' Appendix*.

Application
of steam
power on
rail roads.

(301.) *Application of steam power to Railway carriages.*—The first idea of moving Railway carriages by steam power was that of employing stationary engines, by means

of which and ropes the requisite motion was produced; a method which was successfully practised in one or two early cases, and was even recommended by two highly respectable Civil Engineers, as the best that could be adopted for the Liverpool and Manchester Railway; but this opinion was fortunately overruled by that of the Company's Engineer and the majority of the proprietors.

The inconvenience which first led to the idea of stationary engines was what is called the *skidding* of the wheels. When a carriage is drawn by a horse, or any other first mover, by traces proceeding from the line of the axle, or above or below it, the road itself furnishes a fixed point from which the power proceeds, and towards which the carriage is urged, and at which it must arrive, supposing the power sufficient, if even the wheels were fixed on their axle; but being free, or nearly so at this place, and the circumference meeting with a resistance at the surface of the road, the wheel must necessarily revolve on its axle, and the carriage itself advance forward; all that is requisite for this effect being, that the resistance on the road shall be greater than that at the axle. But if the motive power is in the carriage itself, and its effort be to turn the wheel on its axle, then, unless the resistance at the circumference of the wheel exceeds a certain amount, the wheel will be turned round, but the carriage will remain stationary. This inconvenience was anticipated rather than experienced in the early attempts to work by locomotive engines; the power employed, for want of proper arrangement, frequently turning the wheels back without any, or at least without a proportionate advance of the vehicle. To avoid this imaginary evil the rail was made like a rack, and the wheels with corresponding teeth, and, of course, when the power was applied the carriage was urged forward; but this was found to possess many disadvantages—the motion was rough, and the wear and tear enormous. We believe, however, this practice continued in one or two places for some time.

Another method, intended to avoid the evil above mentioned and to apply steam power to common roads, was, to employ propelling bars from the carriage, the motion of which was made as nearly as possible to imitate the hind legs of a horse, by which a fixed point was found at every stroke of the bar, and the carriage was forced forward. This was exceedingly ingenious; but a serious accident having happened in one of its early experiments, by which several lives were lost, it was laid aside, and the practice discontinued, at least on a large scale. But we have seen a model acting on similar principles with four propellers, which performed its duty remarkably well. It being, however, now well understood that the resistance, not only on a road but on a rail may be rendered amply sufficient to propel the carriages, all the above methods are laid aside, and no thought is now entertained of producing the motion in any other way than that of the direct application of the power to the wheel itself.

(302.) As in most other inventions of great public utility, Treve-thick's loco-motive. different persons have come forward to claim the honour of the first idea, and some idle controversy has been going forward on the subject in a few of our Journals. These, however, are scarcely worth attention. To suggest an idea or to form a model, is certainly one step, but to carry the idea into practice is a greater. At all events it will be sufficient for our purpose to state, that two years after Mr. Trevethick's patent for a high pressure engine, described in (Art. 205.) the inventor con-

Machinery.

To common
roads.

Manufactures.

constructed a Machine of the same kind for the purpose of moving carriages or locomotive engines, which in 1804 was successfully applied on the Rail road at Merthyr Tydvil in South Wales. In this engine the cylinder was placed horizontally, the piston working in the direction of the line of road; the extremity of this rod, by means of a connecting rod, worked cranks placed on the axletree, on which were two cogged wheels fixed on the axle of the hind wheels of the carriage, and by which this axle, together with its wheel fixed to it, were made to revolve, and so long as the friction of the wheel and the rail exceeded the resistance to be overcome, the carriage with its train was urged forward. To this engine was an appendage, no longer thought necessary for road carriages, namely, a fly wheel, which was attached to the axle of the propelling wheel. The fore wheels are described as being capable of turning like the fore wheels of a carriage, so as to enable a director to guide the vehicle. On its first trial it drew after it as many carriages as contained ten tons of iron a distance of nine miles, which stage it performed without any fresh supply of water, and travelled at the rate of five miles per hour.

From this time, now thirty years past, locomotive carriages have become a popular and interesting object; great ingenuity has been displayed, great obstacles and strong prejudices have been overcome, and a work, the Liverpool and Manchester Railway, has been completed, which is not only the admiration of this Country but of the World.

Blinkin-

sop's patent.

In 1811, Mr. Blinkinsop took out his patent for the rack rail and toothed wheels above mentioned, but which failed, for the reasons already stated.

Chapman's patent.

In the following year, 1812, Mr. Chapman took out his patent for working a locomotive engine by a chain extending along the middle of the line of Rail road, from one end to the other. This chain was passed once round a grooved wheel under the centre of the carriage, so that when this grooved wheel was turned by the engine, the chain being incapable of slipping upon it, the carriage was necessarily urged forward. In order to prevent the strain acting on the whole length of the chain, its links were made to fall upon upright forks placed at certain intervals, which between those intervals sustained the tension of the chain produced by the engine. Friction rollers were used to press the chain into the grooves of the wheel, so as to prevent it from slipping. The friction of the chain, however, was found so great that the experiment may be said to have totally failed.

Brunton's patent for road locomotive engines.

In the following year, 1813, Mr. Brunton took out his patent for the propelling rods; but being laid aside by its ingenious inventor, after the accident to which we have alluded, it will not be necessary for us to do more than make this record of the attempt.

Experiment on the adhesion of wheels and rails.

The evils which all these inventions were intended to obviate, were in the following year demonstrated to be merely imaginary. The experiment by which this important point was established was made on the Wylam Rail road; where it was shown that when the road was level, and the rails clean, the friction between the wheels and rail was sufficient, in all kinds of weather, to propel considerable loads. It was first ascertained how much weight the wheels of common carriages would overcome without slipping round on the rail, and having thus the proportion that this bore to the weight, it was found that the weight of the engine would produce sufficient

adhesion or friction to drag after it on the Rail road the requisite number of waggons.

Machinery.

This cleared away a great difficulty, and from that time daily improvements have been made in the construction of carriages for this purpose. It does not appear, however, that the impression was quite removed on this point, as it was thought necessary at first to make use of the friction of all four wheels. Mr. Stephenson's carriage for the Killingsworth Rail road, had its hind and fore wheels connected by an endless chain, the cogged wheels hitherto employed were abandoned, and the rotation produced by an immediate connection of a crank upon them with the piston rods. This engine had two cylinders, one over each pair of wheels, the cranks being so arranged that when the weak point of one crank was in action, the other crank was in its best position; and this relation of the two cranks was preserved by the endless chain above mentioned which passed over both. The boiler was cylindrical, and the chimney proceeding from the end of the carriage was turned upwards in front. In a subsequent engine by the same engineer, the endless chain was abandoned, it having been found that considerable power was lost, and unnecessary friction incurred by this arrangement. It is obvious, indeed, that unless all four wheels are precisely of the same size, the chain will constantly have to drag along the wheel of smallest diameter; and although every possible pains should be taken, and the diameter of all the wheels made perfectly equal at first, which is scarcely possible, yet an unequal degree of wearing would soon destroy the equality, and produce the evils to which we have referred. It would be useless to pass in review the various form of locomotive carriages which have appeared in a few years on different Railways, principally intended for the carriage of goods and heavy luggage; we shall proceed, therefore, at once to a description of the Manchester and Liverpool Railway, which embraces in itself every valuable information on this subject.

Rapid improvement in the application of locomotives.

(303.) *Description of Liverpool and Manchester Railway.*—The extraordinary increase of the Manufactures at Manchester, and the corresponding traffic between that place and Liverpool, rendered necessary a proportional increase in the facility of communication. There were already two lines of Canals between these places, but they were inadequate to the demands of Trade and Commerce, as appears from the following declaration, signed by upwards of one hundred and fifty of the most respectable merchants of Liverpool.

Liverpool and Manchester Railway.

"We, the undersigned merchants and brokers, resident in the Port of Liverpool, do hereby declare, that we have for a long time past experienced great difficulty in obtaining vessels to convey goods from this place to Manchester, and that the delay is highly prejudicial to the Trading and Manufacturing interests at large; that we consider the present establishments for the transport of goods quite inadequate, and that a new line of conveyance has become absolutely necessary to conduct the increasing Trade of the Country with speed, certainty, and economy."

It was accordingly determined to establish a Company for the formation of a double Railway from Liverpool to Manchester; and on the 29th October, 1824, the first prospectus of the Company was issued. The advantages promised by this prospectus, and in an amended one afterwards substituted, were briefly these: A saving of time and of money in the transmission of

Manufac-
tures.

the one thousand tons or more conveyed between the two towns daily; the increase of Commerce and Manufactures by increased facility of intercourse; an improved channel for the conveyance of the Manufactures and agricultural produce of Ireland to the populous towns of Lancaster and York; the carriage of farming produce to the large towns, and the return of lime, manure, &c., to the farmers; speedier conveyance for travellers; and the carriage of coals to Liverpool and Manchester from the valuable mines in the vicinity of St. Helen's, the coals having been heretofore brought to Liverpool principally by Canal, a distance of thirty miles, whilst by the Rail road the distance would be less than half, and the price materially reduced. The quantity of coals consumed annually in Liverpool and Manchester was estimated at one million of tons, and it was calculated that the saving in the price of this necessary article of domestic consumption alone would amount to at least two shillings per ton, or £100,000 annually in the consumption of the two towns.

On the 28th of February, 1825, a petition was brought into Parliament for leave to bring in a Bill, which having gone through several stages, was lost, or rather withdrawn on the 1st of June following; the Canal proprietors having used every possible effort to bring about the result. The question was, however, again brought forward in February of the following year, and was then carried in both Houses; in the Commons by a majority of forty-seven, and in the House of Lords without a division.

Before we enter upon a description of the operations which were commenced in June of the same year, 1826, it will be well to inform the reader of the nature of the difficulties which were to be surmounted. The turnpike road between Liverpool and Manchester measured about thirty-four miles; but by taking as nearly a straight line as possible, the line of the proposed Railway was only thirty-one miles. The Docks at Liverpool are sixty-six feet below the level of Manchester; but the land rises at Edgehill, in the immediate neighbourhood of the former, a hundred and sixty-nine feet above the Docks. This ground is a hundred and three feet above the level of Manchester, and the surface of the land between the two extremes is alternating above and below the level of Edgehill, the highest point being two hundred and five feet above the Docks, and the lowest only twenty-six feet. It was necessary that this line should be rendered as nearly level as possible, for any great ascents or descents would altogether have destroyed the advantages otherwise obtainable by such works. The land also rising so abruptly behind Liverpool, a sudden ascent was necessary, and to avoid interfering with the town itself, it was determined to cut a tunnel under it. This tunnel, which was in some places carried through solid rock, is 1970 yards, and rises one in forty, ascends a hundred and twenty-three feet, at which point it is of course forty-six feet below the top of Edgehill, and twenty-five feet above the artificial level of the rail at Manchester. If this could have been thrown into one general slope, it would have been so inconsiderable as to have been tantamount to a level plane. But this could not be effected, and certain inclinations, both ascending and descending, occur in the course of the line, as in the following dimensions taken from the section:

Inclined plane from Wapping to Edgehill, forming the tunnel 1970 yards, a rise of $\frac{1}{48}$

Level by cutting.	1000 yards.		
Edgehill to Wavertree to Huy-			
ton.	5 $\frac{1}{2}$ miles,	fall	$\frac{1}{1000}$
Wiston inclined plane.	1 $\frac{1}{2}$ do.	rise	$\frac{1}{90}$
Rainhill level	1 $\frac{1}{2}$ do.		
Sutton inclined plane	1 $\frac{1}{2}$ do.	fall	$\frac{1}{90}$
Parr Moss to Sankey canal and			
viaduct	2 $\frac{1}{2}$ do.	fall	$\frac{1}{200}$
Sankey viaduct to Bury Lane. .	6 $\frac{1}{2}$ do.	fall	$\frac{1}{800}$
Chat Moss	5 $\frac{1}{2}$ do.	rise	$\frac{1}{1200}$
Baston, Eccles, Munches. . . .	4 $\frac{1}{2}$ do.	level.	

With these ascents and descents, which, of course, were only admitted to save expense, the labour was still very great. Amongst other operations requiring construction were sixty-three bridges; the cuttings amounted to nearly 720,000,000 cubic yards, and the embankments to 277,000 cubic yards, which, together with tunnelling and other works, presented a charge which none but British merchants could have ventured to have undertaken, and perhaps only British engineers could have executed.

(304.) *Commencement of the work.*—In the following year the work was begun by the draining of Chat Moss. This commenced in June. In September of the same year the first shaft of the Liverpool tunnel was opened; and during the whole of 1827, the formation of it under Liverpool was carried forward with spirit and perseverance. Night and day the excavation proceeded, and many difficulties in the execution of the work had to be overcome. In some places the substance excavated was a soft blue slate, with abundance of water; in other places a wet sand presented itself, which required no slight labour and contrivance for its support, till the masonry which was to form the roof was erected. In passing under Crown Street, near the Botanic Garden, for want of sufficient props, the superincumbent mass, consisting of loose moist earth and sand, fell in from the surface, a depth of thirty feet. On some occasions the miners refused to work, and it not unfrequently required the personal superintendence and encouragement of the engineer to keep them at their posts. But while some portions of the tunnel were excavated under circumstances of no little difficulty and danger, other portions were hewn through a fine red sandstone, clean, dry, and substantial, which required neither props nor artificial arching, the natural rock forming the roof of the excavation. The tunnel was constructed in seven or eight separate lengths communicating with the surface by upright shafts, through which the substance excavated was conveyed away. On the 9th of June, 1828, it was reported to the Directors that the last joining between the several lengths was effected, and that all very serious difficulties in the execution of this branch of the undertaking were surmounted.

In 1828, was principally effected the piling for the foundations of the piers of the great viaduct over the Sankey valley; a business of much labour and cost, but indispensable for the security of the superstructure. About two hundred piles, varying from twenty to thirty feet in length, were driven hard into the foundation site of each of the ten piers. The heavy ram employed to impart the finishing strokes, hoisted up with double purchase and a snail's pace to the summit of the piling-engine, and then falling down like a thunderbolt on the head of the devoted timber, driving it, perhaps, a single half-inch into the stratum below, is well calculated

Preparatory experiments.

to put to the test the virtue of patience, while it illustrates the old adage of "slow and sure."

During 1828, was completed the Company's bridge over the turnpike road and the old mill-dam at Newton, and the operations at Chat Moss were carried on without intermission, embanking at each end, and draining, levelling, &c., in the centre portions.

In the Spring of 1829, the Directors being desirous of proceeding with increased despatch in the execution of the work, instructed the engineer to order the contractors at the principal cuttings throughout the line, to employ two sets of labourers, and to work by night as well as day. The operations accordingly proceeded still more rapidly than heretofore, though it must be allowed at considerably increased expense; and had it not been for the extraordinary wet Summer and Autumn, the earth-work for a complete line of communication between Liverpool and Manchester, might have been accomplished by the end of 1829, or the beginning of 1830, and the Railway laid down for operations within a few months from that period. As it was, very considerable delay was occasioned by the heavy and long-continued rains, besides no trifling expense to the Company in pumping the water from the deep cuttings, which were too apt to assume the appearance of a Canal rather than a Railway.

The principal structure, completed in 1829, was the Company's bridge to carry the Liverpool and Warrington turnpike road over the Railway at Rainhill.

Before the close of 1829, one roadway along the whole extent of Chat Moss was completed; and on the 1st May, 1830, the Rocket steam engine, with a carriage and company, passed over it. That the practicability of carrying the Railway over this Moss should have been questioned, is not to be wondered at, considering that it was in some places from thirty to thirty-five feet deep, and so soft and pulpy that an iron rod would sink through it by its own gravity. The portion of the Moss which presented the most difficulty, was about half a mile on the Eastern border, where an embankment of about twenty feet had to be formed above the natural level. The weight of this embankment resting on a semi-fluid base pressed down the original surface; many thousand cubic yards gradually and silently disappeared before the line of road made any approach to the proposed level. By degrees, however, the whole mass beneath and on each side of this embankment became consolidated by the superincumbent and lateral pressure, and perseverance finally completed the work.

In September, 1829, was commenced the Company's bridge over the Irwell; the last great structure on the line of Railway from Liverpool to Manchester.

(305.) At this time it had not been determined by what means the carriages were to be transported along the rail; whether by horses, by stationary steam engines, or by locomotives.

The great theatre of practical experience on Railways, was previously the Stockton and Darlington line, and the Railways in the vicinity of Newcastle-on-Tyne. All the modes heretofore in use of propelling carriages on Railways, namely, by horses, by locomotives, and by fixed engines, had been there exemplified, but facts were wanted to lead to a correct decision, and personal observation seemed necessary in order to arrive at a satisfactory result. The Directors accordingly appointed two of their own Body, accompanied by Mr. Booth, their Treasurer, to proceed to Darlington and the neighbourhood of

Newcastle, to obtain, on the spot, the requisite information, and to report the same to the Board, with their opinion on the subject. This journey of inspection took place in the beginning of October, 1828, and the deputation returned with a fund of information, but of so mixed, and, in some respects, of so contradictory a nature, that the great question as to the comparative merits of locomotive and fixed engines was as far from being settled as ever. One step only was gained; the deputation were perfectly convinced that for the immense traffic to be anticipated on the Liverpool and Manchester line, horses were out of the question. In these circumstances the Directors resolved on calling in the assistance of two professional engineers, to enable them to determine which it would be best to adopt, fixed or locomotive engines; and the gentlemen selected for this purpose were Messrs. Walker and Rastrick.

On the 9th of March, 1830, two separate Reports from these engineers were laid before the Directors. The merits and demerits of each system were therein very fully and fairly stated; and in the opinions of Messrs. Walker and Rastrick, they were pretty equally balanced. The cost of an establishment of fixed engines between Liverpool and Manchester, they were of opinion, would be something greater than of locomotives to do the same work; but the annual charge, including interest on capital, they computed, would be less on a system of fixed engines than with locomotives. The cost of moving a ton of goods thirty miles, that is, from Liverpool to Manchester, by fixed engines, they estimated at 6.40d. and by locomotives at 8.36d. supposing in each case a profitable traffic both ways. But with a system of locomotives, the cost of the first establishment need only be proportioned to the demands of the trade, while with stationary engines an outlay for a complete establishment would be required in the first instance. And it was further to be considered, that there appeared more ground for expecting improvements in the construction and working of locomotives than of stationary engines. On the whole, however, and looking especially at the computed annual charge of working the road on the two systems on a large scale, Messrs. Walker and Rastrick were of opinion that fixed engines were preferable, and accordingly recommended their adoption to the Directors.

Mr. Stephenson, the Company's engineer, had always been in favour of locomotive engines; and notwithstanding this decision of Messrs. Walker and Rastrick he was still decidedly of opinion, that they would be found to furnish the most economical and most convenient moving power that could be employed. Moreover, the inclination of a majority of the Directors continued in favour of locomotives, provided they could be so constructed as to consume their own smoke, (agreeably to the provisions of the Railway Act,) and of an adequate power, and of a less weight than the engines then in use, which were generally from eight to ten tons, which was supposed to produce injury to the Rail road, and to incur a proportional expense in keeping it in repair. The Directors determined, therefore, to obtain, if possible, locomotive engines of improved construction that should be of lighter weight. In order to effect this, a premium was offered of £500 for the most approved carriage to be constructed and submitted to trial early in October of 1829.

This premium, as might be expected, acted as a great stimulus to exertion, not merely for obtaining the

Manufactures.

pecuniary, but the honorary reward, which would attend success in such a trial. The day ultimately appointed was the 6th of October. The umpires were Messrs. Rastrick and Wood, Civil engineers, with J. Kennedy, Esq. of Manchester. The portion of the Railway set apart for the trial was on the Manchester side of Rainhill bridge, about nine miles from Liverpool, where the Railway runs about two or three miles on a dead level.

Early in the day a great number of persons were collected from all parts to witness this extraordinary exhibition; many from great distances, principally engineers, scientific men, and amateurs in Science, most of them well qualified to judge not only of the merits of the different engines, but also of the advantages of the great national question with which the experiments were connected. The number of steam locomotives were four, as follows:

Pl. xxi.
Fig. 1, 2, 6,
7.

1. Messrs. Braithwaite and Ericson, of London. This engine was named the "Novelty," and weighed empty two tons fifteen hundred weight, represented in pl. xxi. fig. 1.
2. Mr. Ackworth, of Darlington, the "Sans Pareil," weighing four tons eight and a half hundred weight; fig. 2.
3. Mr. Robert Stephenson, the "Rocket," weighing four tons three hundred weight; fig. 6.
4. Mr. Brandreth, of Edinburgh, the "Perseverance," weighing two tons seventeen hundred weight. The figure of this engine is not given. Fig. 7 is a representation of the present general and most approved form of locomotive on the Manchester Railway.

(306.) The Rocket first appeared in running trim, but not for the grand trial, and drew a weight besides itself of twelve tons nine hundred weight, at a rate exceeding ten miles per hour, and when relieved of its load, its speed was eighteen miles per hour.

On the following day, the Novelty showed some preliminary practice; the engine without a load is said to have started into a pace of twenty-eight miles per hour, and with its load at twenty and three-quarter miles per hour; but the distance is not stated. At this time it does not appear that the conditions were well known, by which the merits of the engines were to be determined. These were, however, now propagated, viz. that the engines were not to exceed in weight six tons; that each was to draw three times its own weight at first starting, and to go a distance of seventy miles at not less than ten miles per hour.

Report of
the experi-
ments.

The grand trial now commenced. The Novelty commenced, but unfortunately bursting one of its pipes, failed of accomplishing the journey. The Sans Pareil met with a similar accident and was withdrawn, after it had performed twenty-two and a half miles in one hour and thirty-seven minutes, and was bidding fair to carry off the prize; its greatest speed was fifteen miles per hour. The Perseverance seems to have had no chance of success. The above two, and the Rocket, were therefore the only engines which may be said to have contended, or to have had any chance of obtaining the prize, which was finally awarded to the Rocket, this engine having run the whole distance twice, the first time in two hours, fourteen minutes, eight seconds, the second in two hours, six minutes, forty-nine seconds. The speed averaging in one case eleven and a half miles per hour, and in the other thirteen four-

tenths. Its greatest speed was twenty-nine miles per hour, and its least eleven and a half miles. Machinery.

In a case like that above detailed, every exertion would be made; the engines would be brought to the ground in the best working trim, and we may, perhaps, expect some little exaggeration in unauthorized reports of their performance, which were very numerous; but sufficient was done to show that, notwithstanding much had been effected, more might be anticipated, and this expectation has been fully borne out by the practice of the last three years. In these trials the engines were only called upon to drag three times their own weight, and the best speed of the winning engine, the Rocket, was twelve and a half miles per hour, while the engines at present, on their common duty, drag ten or twelve times their own weight, and generally preserve a medium rate of twenty miles an hour, and the train for passengers twenty-four miles per hour.

From this date the question between locomotive and fixed engines was considered to be practically settled. The fitness of locomotives for the purposes of travelling at almost any speed that could be desired was strikingly exemplified. But there still remained one point to be settled, namely, the *kind of power* to be employed in ascending the inclined planes of Whiston and Sutton. These planes are each a mile and a half long, with an inclination of three-eighths of an inch to a yard, being a rise of one in ninety-six. Stationary engines on the summit, with ropes passing over sheaves or pulleys along the whole ascent, are the means resorted to at the inclined plane in the Liverpool Tunnel; also on the Darlington inclined planes, and at the Collieries in the North. It was quite evident, however, that such a plan of operations in the centre of the Manchester and Liverpool line, with the interruption to be expected from a change of the moving power, not to mention the danger always to be apprehended from a system of ropes and pulleys, was to be avoided if possible. It became an object, therefore, of great interest to ascertain the power of the new locomotives on the planes in question. During the trials at Rainhill, in October, 1830, the Rocket frequently ascended the Whiston inclined plane with a carriage holding from twenty to thirty passengers, at a speed of from fifteen to eighteen miles per hour; and the ease and regularity with which this was effected produced a general impression, that even up inclined planes the locomotive engine would be the power employed. Indeed, the feeling at the moment was very prevalent, that it was immaterial whether the engine travelled up an inclined plane or on a level; but subsequent experiments have fully established, what it would have been only reasonable to assume *a priori*, that the power of an engine diminishes in proportion to the degree in which the plane is inclined, till it reaches a point, when, adhesion terminating, the wheels turn round without advancing; and, therefore, without assistance of some sort up such inclined planes as those of Whiston and Sutton, an engine must go either at a less speed or draw a less weight. For example: the Comet locomotive, a new engine on the same plan as the Rocket, ascended the Whiston inclined plane with about twenty-six tons behind it, with a speed diminishing from the rate of between sixteen and eighteen miles at the commencement, to about three or four miles per hour before it reached the top; this is the unavoidable consequence of the inclination, which necessarily throws, in this case, where the slope is one in ninety-six, a ninety-sixth part

Abstract of disbursements.

of the load upon the engine, an amount far exceeding the whole friction on a level plane.

(307.) *Abstract of expenses.*—The following general abstract of the expenditure of the Railway, to the 31st of May, 1830, showing the cost of the different branches of the undertaking, may be interesting to the reader.

	£.	s.	d.
Advertising account	332	1	4
Brickmaking account	9,724	4	4
Bridge account	99,065	11	9

The number of bridges is 63, of which one is of 9, a second of 4, and a third and fourth of 2 arches. The rest are of one arch each.

Charge for direction	1,911	0	0
Charge for fencing	10,202	16	5
Cart establishment	461	6	3
Chat Moss account	27,719	11	10

The embankments included under this head consist of about 277,000 cubic yards of raw moss earth, in the formation of which about 677,000 cubic yards of raw moss earth have been used; the difference of measurement being occasioned by the squeezing out of the superabundant water and consequent consolidation of the moss. The expenditure on this part of the line has been less than the average expenditure.

Cutting and embankments	199,763	8	0
-------------------------------	---------	---	---

Under this head is comprised the earth-work on the whole line, exclusive of the Chat Moss district. The cutting somewhat exceeds the embankments; the surplus is principally deposited along the border of the Great Kenyon cutting. The excavations consist of about 722,000 cubic yards of rock and shale, and about 2,006,000 cubic yards of marl, earth, and sand. This aggregate moss has been removed to various distances, from a few furlongs to between three or four miles; and no inconsiderable portion of it has been hoisted up by Machinery, from a depth of from 30 to 60 feet, to be deposited on the surface above, either to remain in permanent spoil banks, or to be afterwards carried to the next embankment.

Carrying department, comprising account expended in land and building for stations and depots, warehouses, offices, &c. at the Liverpool end	£35,538	0	0
Expended at the Manchester station	6,159	0	0
Side tunnel	2,485	0	0
Gas light account, including cost of pipes, gasometer, &c.	1,046	0	0

Formation of the road	56,219	11	4
	20,568	15	5

By this is understood what is termed ballasting the road, that is, depositing a layer of broken rock and sand about two feet thick; viz. one foot below the blocks and one foot distributed between them, serving to keep them firm in their places. Spiking down the iron chains to the blocks or sleepers, fastening the rails to the chains with iron keys, and adjusting the Railway to the exact width, and curve, and level, come under this head of expenditure.

Rail account	69,912	0	2
--------------------	--------	---	---

This expenditure comprises the following items:

Rails for a double way from Liverpool to Manchester, with additional lines of communication, and additional side

	£739,185	5	0	

This account, it will be observed, reaches only to May 31, 1830, at which time the work was not complete; and it appears by a Report of the Directors that in December 1831, the capital expended on the whole work amounted (including engines, coaches, waggons, &c.) to £992,054. 3s. 6d.

(308.) Taking, now, a view of the work as completed, the entrance in the Company's yard at Wapping, Liverpool, is by an open cutting twenty-two feet deep and forty-six feet wide, affording space for four lines of Railway; between these lines are pillars supporting the floors of the Company's warehouses, to which there are hatchways or trap doors, allowing the waggons placed below to be readily loaded and unloaded. Here the inclined plane and tunnel commence: the breadth is twenty-two feet, side walls five feet high, with a semicircular arch of eleven feet radius, making the height sixteen feet, and the length, as before stated, one thousand nine hundred and seventy yards, rising, on an inclination of one in forty-eight, one hundred and twenty-three feet. This tunnel, through its whole length, is furnished with gas-lights, suspended from the centre of the arched roof, at a distance of twenty-five yards; and the sides and roof are whitewashed, the better to reflect the light. At the upper end, the tunnel terminates in a large open area about forty-six feet below the summit of Edgehill, cut out of the solid rock, and surmounted on every side by walls and battlements. From this area, another shorter tunnel branches quite distinct from the larger one, which communicates with the upper part of Liverpool. Its dimensions are two hundred and ninety yards long, five wide, and twelve feet high. It terminates in the Company's premises in Crown Street, which is the principal station for the Railway coaches. Above this area are erected two lofty chimneys belonging to the stationary steam engines at this place for bringing the carriages up the inclined plane; they are each one hundred feet high, and are built to represent columns with handsome capitals.

From this station, proceeding Eastward, the road

General view of the work as completed.

Manufac-
tures.

passes through a Moorish archway; this connects the two engine-houses, and forms the grand entrance of the Liverpool stations. The road in this part curves slightly, but is perfectly level for one thousand yards; it then falls, as before stated, for more than five miles, on a slope of four feet to a mile, or $\frac{1}{100}$. About half a mile to the North of the village Wavertree a passage is cut through a steep eminence called Olive Mount; this cutting is more than two miles in extent, in solid rock, some parts of which are seventy feet below the surface, and only sufficiently wide for the two trains of carriages to pass each other. It winds gently round to the South-East, and the view is bounded by the perpendicular rock on either side. Four hundred and eighty thousand cubic yards of stone have been removed in forming this excavation, a good deal of which has been employed in building the bridges, walls, &c., in this part of the line; the bridges here being principally to form communications between the roads and farms cut through by the Railway.

Emerging from the Olive Mount cutting, the road is thence artificially raised by the great Roby embankment which is nearly three miles in length, varying in height from fifteen to forty-five feet, and in breadth at the base from sixty to one hundred and thirty-five feet. This is formed of the materials dug out from the various excavations. The quantity employed was five hundred and fifty thousand cubic yards. After passing the Roby embankment, the Railway crosses, by means of a bridge, over the Huyton turnpike road; and proceeds in a slightly curved direction to Whiston, between seven and eight miles from the station at Liverpool. Here the Rail road continues for a mile and a half in a straight line, having in its length an inclination of one in ninety-six; at the top of this inclined plane the road runs nearly two miles on an exact level, produced by the excavation of two hundred and twenty thousand cubic yards. Over this part, called Rainhill level, the turnpike road between Liverpool and Manchester proceeds, crossing the line of Railway at an acute angle of 34° by means of a substantial stone bridge. At the other side of this two miles of level is the Sutton inclined plane, which is similar in extent and inclination to the Whiston plane descending from Rainhill in the opposite direction. A little distance thence is Parr Moss, over which the road is carried. This moss is twenty feet deep, and extends three-quarters of a mile in the line. The materials for the road which forms the Railway on this unsubstantial matter were obtained from the excavations of the Sutton inclined plane which produces one hundred and forty-four thousand cubic yards of clay and stone. The heavy deposit sank to the bottom, and now forms with the moss a firm embankment, in reality twenty-five feet high, though only four or five feet above the surface of the other parts of the moss. Not very far from this, and about half way between Liverpool and Manchester, is the valley of the Sankey, at the bottom of which the Canal flows. Over this valley, without interruption to its navigation, the Railway is carried along a magnificent viaduct, supported on nine arches; each arch is fifty feet span, and varies from sixty to seventy feet in height; these are built principally of brick with stone facings: the width of the Railway between the parapets is twenty-five feet. The piling for the foundation of the piers of this great viaduct was a business of much labour and cost, but indispensable for the security of the superstructure.

The approach to this structure is by an embankment attaining to the height of sixty feet. This is formed principally of clay dug out from the high lands on the borders of the valley. Not far from Sankey is Newton, near to which town the Railway crosses a narrow valley by a short but lofty embankment, and by a handsome bridge of four arches, each having forty feet span. The turnpike road from Newton to Warrington passes under one of these arches, and beneath another flows a small river. At Kenyon, a few miles beyond Newton, is an excavation of greater magnitude than any other on the line, eight hundred thousand cubic yards of clay and sand having been dug out of it. Near the end of this cutting, the Kenyon and Leigh Junction Railway joins the Liverpool and Manchester line by two branches, pointing to the two towns respectively. This Railway joins the Bolton and Leigh line, and thus forms the connecting link between Bolton, Liverpool, and Manchester. After the Kenyon excavation is the Brosely embankment, and a little beyond commences the Chat Moss. The difficulties overcome here have already been briefly described; and now, by the ingenuity and perseverance of man, trains of carriages of many tons weight are constantly passing and repassing over a bog, which originally would not allow of a person walking over it except in the driest weather. About a mile from the extremity of the moss, the Railway crosses the Duke of Bridgewater's canal, by a neat stone bridge of two arches. Some little distance beyond is the village of Eccles, four miles from Manchester. Through this extent is an excavation from which two hundred and ninety-five thousand cubic yards of earth have been dug out. At Manchester the Railway crosses the river Irwell by a very handsome stone bridge, of two arches of sixty-five feet span, thirty feet from the water; and then over a series of twenty-two arches, and a bridge, to the Company's station in Water Street. The whole line of road is a distance of thirty-one miles from the Liverpool station. The Railway is there on a level with the second story of the Company's warehouses, and by six large doors, or gateways, the waggons may be rolled into them and conveniently discharged or loaded under cover.

We have thus brought up the particulars of this great national undertaking to the end of May, 1830. In the following month preparations began to be made for the opening, which was expected to take place in the latter end of the Summer. On the 14th of June, in that year, an experiment was made as a measure to the anticipated opening, well calculated to exhibit the peculiar character of Railway conveyance, and to put to the test the capabilities of the locomotive engine, both on a level and up inclined planes. On this occasion, the Directors, in two carriages, proceeded on a journey of inspection from Liverpool to Manchester and back. The Arrow, another of Mr. Stephenson's engines, was the proving power. The gross weight drawn was about thirty-three tons, consisting as follows:

	Tons.
Stone in seven waggons	20
Weight of waggons	7
Engine tender and six persons	3
Two carriages and twenty persons ..	3
	33

With this load she travelled from the engine-house, Liverpool, to Old Field Lane Bridge, Salford, Manchester, the distance being about twenty-nine miles, in

Experi-
ments pre-
paratory to
opening the
works.

Manufac-
tures.

two hours and twenty-five minutes, including two stoppages to take in water. Up the Whiston inclined plane she was assisted by the Dart, an engine of similar construction and power; and the first quarter of a mile of the ascent was accomplished at a speed of seventeen miles per hour before the summit was gained, the mile and a half being accomplished in twelve minutes; the average speed being, therefore, seven and a half miles per hour. At the top of the ascent the Dart was unyoked, and the Arrow proceeded with her cargo along the straight and level plane at Rainhill at the rate of sixteen miles per hour. On the return from Manchester the engine-tender and the two carriages, with passengers, constituted the whole load drawn. The first nine and a quarter miles from Old Field Lane Bridge to Glazebrook Bridge, including the Chat Moss district, were accomplished at a speed averaging from nineteen to twenty miles per hour. The whole distance was accomplished in one hour and forty-six minutes, including stoppages, the speed generally varying from eighteen to twenty-five miles and upwards per hour, and the engine not working to her full power a great portion of the way. The speed up the Sutton inclined plane (without any assistant engine) averaged more than fifteen miles per hour. The day was wet, and the rails in some places were very dirty; the whole performance, therefore, took place under circumstances by no means favourable, but the result was highly satisfactory.

Opening
the Rail-
way.

(309.) From this time, preparations were going forward, and every thing arranged for the opening, which was ordered to take place on the 15th of September. This was not a case of ordinary occurrence, and it was the wish of all concerned that this important ceremonial should be worthy of the occasion; accordingly, every necessary preparation was made to give effect to the scene, and every pains taken to avoid such accidents as might be expected from the concourse of people which would doubtless be present. All loose stones and rubbish which lay at the mouths of the tunnels, and on different parts, were removed; the rails were well swept, and strong paling was erected on each side of the deep cuttings for several miles. A strong Body of police and some military were in attendance, to preserve order, and to keep the Railway clear. The persons to whom places were assigned in the procession were requested to assemble at the Company's Station in Crown Street, at half-past nine in the morning. Each engine and its train of carriages had distinguishing flags; the colours of the admission cards corresponded with those of the flags, and every card bore the number of the seat which was allotted to its possessor. The number of locomotive engines employed on the occasion was eight, named as follows:—the Northumbrian, the Phoenix, the North Star, the Rocket, the Dart, the Comet, the Arrow, the Meteor. The whole of these engines had been built by Messrs. Stephenson and Co., of Newcastle; the Rocket being the same that bore off the prize in the preceding year: the rest were constructed on a similar plan, varying only in dimensions, and in some indifferent matters of arrangement. It was expected that three engines also, constructed by Messrs. Braithwaite and Ericsson, on their patent principle, would have been in readiness, namely, the far-famed Novelty, and two new engines which these engineers had contracted to build for the Railway Company, not exceeding five tons weight, and capable of drawing forty tons gross, at the rate of fifteen miles an hour; the consumption of coke

not to exceed half a pound weight per ton per mile. But these engines not having arrived from London early enough to be subjected to a preliminary trial, the Directors thought it would not be prudent to allow them to make part of a procession which it was of the utmost consequence should be exposed to as few risks of failure as possible. The whole of Messrs. Stephenson and Co.'s engines had, we believe, been repeatedly tried, and with success, several weeks before.

Machinery.

The Northumbrian was appointed to take the lead of the procession, drawing a splendid carriage, appropriated to the reception of the Duke of Wellington, Sir Robert Peel, and about thirty other distinguished individuals, who honoured the ceremony with their presence. Each of the other locomotives drew four carriages, containing between eighty and ninety persons; so that the total number of individuals accommodated with seats in the procession must have been about six hundred.

At twenty minutes to eleven o'clock the procession commenced its progress towards Manchester, the Northumbrian taking exclusively one of the two lines of rail, and the rest of the engines the other. The brilliancy of the *cortège*, the novelty of the sight, considerations of the almost boundless advantages of the stupendous power about to be put in operation, gave to the spectacle an interest unparalleled. On every side the tumultuous voice of praise was heard, and countless thousands waved their hats to cheer on the sons of enterprise in this their crowning effort. The engines proceeded at a moderate speed towards Wavertree Lane, when increased power having been added, they went forward with great swiftness, and thousands fell back, whom all the previous efforts of a formidable police could not move from the road. Numerous booths and vehicles lined the various roads, and were densely crowded. After passing Wavertree Lane, the procession entered the deep ravine at Olive Mount, and the eye of the passenger could scarcely find time to rest on the multitudes that lined the roads, or admire the various bridges thrown across this great monument of human labour. Shortly afterwards Rainhill bridge was neared, and the inclined plane of Sutton began to be ascended at a more slackened rate. The summit was soon gained, and twenty-four miles an hour became the maximum of the speed. About noon the procession passed over the Sankey viaduct. The scene at this part was particularly striking. The fields below were occupied by thousands, who cheered as the procession passed over the stupendous edifice; carriages filled the narrow lanes, and vessels in the water had been detained, in order that their crews might gaze up at the gorgeous pageant passing far above their mast-heads. Shortly after it passed the Borough of Newton, and reached Parkside, seventeen miles from Liverpool. Here the engines stopped to take in a supply of water and fuel, and many of the company having alighted in the interval, were walking about congratulating each other on the truly delightful treat they were enjoying, all hearts bounding with joyous excitement, and every tongue eloquent in the praise of the gigantic work now completed, and the advantages and pleasures it afforded, when the scene was in a moment changed from joy to mourning. Every thing was again nearly ready to proceed, and some of the line of carriages which had been left a little behind were already in motion moving forwards with great speed. Mr. Huskisson was standing near the Duke

Manufac-
tures.

of Wellington's carriage inside the line, and seeing the other carriages approaching with fearful rapidity, he lost his presence of mind, was thrown down by them on their approach, and the engine passed over his leg and thigh, which were so dreadfully injured that, after lingering a few hours, he expired. This accident, of course, threw a general gloom over the proceedings; the journey, however, was continued, although considerably delayed; and the engines having reached Manchester, returned again to Liverpool in the evening.

Commence-
ment of
regular
traffic.

(310.) On the following morning, the regular business of the Railway commenced. The Northumbrian left Liverpool with one hundred and thirty passengers, and arrived at Manchester in one hour and fifty minutes; in the evening it returned with one hundred and twenty passengers and three tons of luggage in an hour and forty-eight minutes: this was the first journey for hire. The next day six carriages commenced running regularly between the two towns, at three separate hours of the day; but which from the number of passengers were necessarily soon increased. The whole number of passengers between the 17th of September and December 31, 1830, was 70,000: between the 1st of January and 1st of July, 1831, 188,726; and in the next six months the numbers were increased to 256,321: a like astonishing increase took place in the carriage of merchandise and luggage, as will be seen by the following abstract of the first year's traffic, receipts, and disbursements; viz. from January 1 to December 31, 1831.

1st of January to 1st of July, 1831.

In 1832 there was a decrease in the number of passengers, but a further increase in luggage, and which now appears to average 1300 tons daily.

(311.) With respect to the capabilities of the engines, these appear to show a corresponding improvement. In the trials made with the experimental carriages they were required to draw only three times their own weight; they now draw ten, twelve, and even fifteen times their own weight. These carriages, also, were called upon to perform ten miles an hour; the common speed is now nearly twenty. On this head the following experiments made by Dr. Lardner are very satisfactory; since he was a disinterested man of great practical and theoretical Science, who had permission from the Directors to ascertain every fact, and examine into every circumstance stated in the following details of three following experiments.

First experiment.—On Saturday, the 5th of May, 1831, the engine called the Victory took 20 waggons of merchandise, weighing gross 92 tons, 19 hundred weight, 1 quarter, together with the tender containing fuel and water, of the weight of which I have no account, from Liverpool to Manchester, (30 miles,) in 1 hour, 34 minutes, 45 seconds. The train stopped to take in water half way for 10 minutes, not included in the above-mentioned time. On the inclined plane rising 1 in 96, and extending 1½ mile, the engine was assisted by another engine called the Samson, and the ascent was performed in 9 minutes. At starting, the fire-place was well filled with coke, and the coke supplied to the tender accurately weighed. On arriving at Manchester, the fire-place was again filled, and the coke remaining in the tender weighed. The consumption was found to amount to 929 pounds net weight, being at the rate of one-third of a pound per ton per mile.

Speed on the level was 18 miles an hour; on a fall of 4 feet in a mile, 21½ miles an hour; fall of 6 feet in a mile 25½ miles an hour; on the rise over Chat Moss 8 feet in a mile, 17½ miles an hour; on level ground sheltered from the wind, 20 miles an hour. The wind was moderate, but direct ahead. The working wheels slipped three times on Chat Moss, and the train was retarded from 2 to 3 minutes.

The engine on this occasion was not examined

Details of
perform-
ance by Dr
Lardner.

First experi-
ment.

Manufactures.

Second experiment.

Third experiment.

Remarks.

before or after the journey, but was presumed to be in good working order.

Second experiment.—On Tuesday the 8th of May, the same engine performed the same journey, with 20 waggons, weighing gross 90 tons, 7 hundred weight, 2 quarters, exclusive of the unascertained weight of the tender. The time of the journey was 1 hour 41 minutes.

The consumption of coke 1040 pounds net weight, estimated as before. Rate of speed:—

Level	17½ miles per hour.
Fall of 4 feet in a mile	22 ditto
Fall of 6 ditto	22½ ditto
Rise of 8 ditto	15 ditto

On this occasion there was a high wind ahead on the quarter, and the connecting rod worked hot, owing to having been keyed too tight. On arriving at Manchester, the cylinders were ordered to be opened, and it was found that the pistons were so loose, that the steam blew through the cylinders with great violence. By this cause, therefore, the Machine was robbed of a part of its power during the journey; and this circumstance may explain the slight decrease in speed, and increase in the consumption of fuel, with a lighter load in this journey compared with that performed on the 5th of May.

The Victory weighs 8 tons 2 hundred weight, of which 5 tons 4 hundred weight rest on the drawing wheels. The cylinders are 11 inches diameter, and 16 inches stroke, and the diameter of the drawing wheels is 5 feet.

Third experiment.—On the 29th of May, the engine called the Sampson (weighing 10 tons 2 hundred weight, with 14-inch cylinders, and 16-inch stroke, wheels 4 feet 6 inches diameter, both pairs being worked by the engine, steam 50 pounds pressure, 130 tubes) was attached to 50 waggons laden with merchandise, net weight about 150 tons, gross weight, including waggons, tender, &c. 223 tons 6 hundred weight. The engine with this load travelled from Liverpool to Manchester (30 miles) in 2 hours and 40 minutes, exclusive of delays upon the road for watering &c., being at the rate of nearly 12 miles an hour. The speed varies according to the inclinations of the road. Upon a level it was 12 miles an hour; upon a descent of 6 feet in a mile it was 16 miles an hour; upon a rise of 8 feet in a mile, it was about 9 miles an hour. The weather was calm, the rails very wet, but the wheels did not slip even in the slowest speed, except at starting, the rail being at that place soiled and greasy with the slime and dirt to which they are always exposed at the stations. The coke consumed in this journey, exclusive of what was raised in getting up the steam, was 1762 pounds, being at the rate of a quarter of a pound per ton per mile.

From the above experiments it appears, that a locomotive engine in good working order, with its full complement of load, is capable of transporting weights at an expense in fuel amounting to about four ounces of coke per ton per mile. The attendance required on the journey is that of an engine-man and a fire-boy; the former being paid 1s. 6d. for each trip of 30 miles, and the latter 1s. In practice, however, we are to consider, that it rarely happens that the full complement of load can be sent with the engines; and when lesser loads are transported, the *proportionate expense* must, for obvious reasons, be greater. During the previous Winter, the loads commonly transported by engines like the Victory, were about 35 tons, latterly they have been considerably increased; and at present, with the assist-

VOL. VII.

ance of another engine on the inclined plane, the ordinary load is, we are informed, about 100 tons gross.—*Machinery*
Lardner, *Lectures on the Steam Engine*.

Having thus given a concise sketch, first of the operations attending the construction and formation of the Railway, the expense attending that construction, and the successes which have attended the adoption of the locomotive engine, the result of the first year's revenue and disbursements, and the above well-authenticated account of three journeys, which are under the common order of working at present, we shall now proceed to give a description of engines, carriages, &c.

(312.) *Description of the engines.*—We have not hitherto interrupted the general detail of the Railway operations of the engines. by any particular description of the carriages; it will be proper, however, now to describe the nature of their construction. The Rocket is represented in plate xxi. fig. 6. It is supported on four wheels; the principal part of the weight being thrown on one pair which are worked by the engine by means of the crank shown in the figure. The boiler A consists of cylinders six feet long with flat ends. The chimney ascends from the end in front, and to the other is attached a square box B, the bottom of which is furnished with the grate on which the fuel is placed. This box is composed of two castings of iron, one contained within the other, having between them a space about 3 inches in breadth; the magnitude of the box being 3 feet in length, 2 feet in width, and 3 feet in depth. The casing which surrounds the box communicates with the lower part of the boiler by a pipe marked C; and the same casing at the top of the box communicates with the upper part of the boiler by another pipe marked D, where water is admitted into the boiler, therefore it flows freely through the pipe C into the casing which surrounds the furnace or fire-box, and fills this casing to the same level as that which it has in the boiler. When the engine is at work the boiler is kept about half filled with water; and, consequently, the casing surrounding the furnace is completely filled. The steam which is generated in the water contained in the casing, finds its exit through the pipe D, and escapes into the upper part of the boiler. A section of the engine, taken at right angles to its length, is represented at fig. 5. Through the lower part of the boiler pass a number of copper tubes of small size, which communicate at one end with the fire-box, and at the other with the chimney, and form a passage for the heated air from the furnace to the chimney, the ignited fuel spreads on the grate at the bottom of the fire-box, disperses its heat by radiation, and acts in this manner on the whole surface of the casing surrounding the fire-box; and thus raises the temperature of the thin shell of water contained in that casing. The chief part of the water in the casing being lower in its position than the water in the boiler, acquires a tendency to ascend when heated, and passes into the boiler; so that a constant circulation of the heated water is maintained, and the water in the boiler must necessarily be kept at nearly the same temperature as the water in the casing. The air which passes through the burning fuel, and which fills the fire-box, is carried by the draught through the tubes which extend through the lower part of the boiler, and as these tubes are surrounded on every side with the water contained in the boiler, this air transmits its heat through these tubes to the water, and finally issues into the chimney, and rises by the draught. The power of this furnace must

2 L

Manufac-
tures.

Pl. xxi.
Fig. 5.

Fig. 6.

Fig. 2.

Fig. 1, 3.

necessarily depend on the power of the draught in the chimney, and to increase this, and at the same time dispose of the waste steam after it has worked the piston, this steam is carried off by a pipe L, which passes from the cylinder to the chimney, and there escapes in a jet which is thrown upwards. By the velocity with which it issues from this jet, and by its great comparative levity, it produces a strong current upwards in the chimney, and thus gives force to the draught of the furnace. In fig. 5, the grate bars are represented at the bottom of the fire-box at F. There are two cylinders, one only of which appears in the elevation, fig. 6. The spokes which these cylinders work on as cranks, are placed at right angles on the wheels, which latter are fixed on one common axle which revolves with them. In this engine, the surface of water surrounding the fire-box exposed to the action of the radiant heat, amounted to twenty square feet, which received heat from a surface of six square feet of burning fuel on the bars. The surface exposed to the action of the heated air amounted to one hundred and eighteen square feet. The engine drew after it another carriage, containing fuel and water; the fuel used was coke, for the purpose of avoiding the production of smoke.

The next experimental engine, the Sans Pareil, is represented in fig. 2, and the horizontal section in fig. 4. The draught here is produced in the same manner as in the engine above described, but the boiler differs from the former very considerably. In this a recurved tube passes through the boiler. In the horizontal section, D represents the opening of the furnace at the end of the boiler by the side of the chimney. At A are shown the grated bars supporting the fuel, and a curved tube, passing through the boiler and terminating in the chimney, is seen at B, the direction of the draught being denoted by the arrow. C is a section of the chimney, the cylinders are placed as in the Rocket on each side the boiler, but vertically, each working the connected wheels on one side, and acting on spokes on the opposite sides, at right angles with each other. The space, in which the grate and flue are placed, diminishes in diameter as it approaches the chimney. At the mouth where the grate is placed, its diameter is two feet, and is gradually reduced to fifteen inches. The grate bars extend five feet into the tube. The surface of water exposed to the radiant heat of the fire, is sixteen square feet, and that exposed to the heated air and flame seventy-five square feet. The surface of the grate which sustained the fuel ten square feet.

The Novelty is represented in fig. 1, and a section of the generator and boiler in fig. 3; the corresponding parts in the two figures are marked by the same letters. A is the generator or receiver, containing the steam which works the engine; this communicates with a lower generator B, which extends in a horizontal direction the whole length of the carriage. Within the generator A is contained the furnace F, which communicates in a tube C, carried up through the generator, and terminated at top by sliding shutters which exclude the air, and which are only opened to supply fuel to the grate F. Below the grate the furnace is not open as usual to the atmosphere, but communicates by a tube E with bellows, which are worked by the engine, and which forces a constant stream of air, by the tube E, through the fuel on F, so as to keep that fuel in a high state of combustion. The heated air, contained in the furnace F, is driven on by the same force through the small

curved tube e, which circulates like a worm through the horizontal generator or receiver, tapering gradually till reduced to very small dimensions, when it finally issues into the chimney. The air, in passing along this tube, imparts its heat to the water, by which the tube is surrounded, and is brought to a considerably reduced temperature when discharged into the chimney. The cylinder, which is represented at K, works one pair of wheels by means of a bell crank, the other pair, when necessary, being connected with them. In this engine, the area, or the surface of burning fuel, is less than two square feet, the surface exposed to radiant heat nine and a half square feet, and the surface of water exposed to the heated air about thirty-three square feet.

Of these different boilers, that first described in the Rocket appears decidedly the best, although it has some imperfections, arising from the expansion of the tubes; it is, however, the one most preferred, and is the invention of Mr. Booth, the Treasurer of the Company, but the principle has been still further extended in the engines more recently constructed by Mr. Stephenson. Indeed, from the time of the first commencement to the present time, scarcely a month has passed without suggesting some changes in the detail; by which fuel is saved, the production of steam rendered more rapid, the wear of the engine diminished, and the strength of the different parts rendered more truly proportionate to the amount of strain, or the deteriorating action to which they are exposed. The consumption of fuel in the Rocket, to transfer a ton a mile, was 2.41 pounds of coke, and in the Sans Pareil, 2.47 pounds; in subsequent engines it was reduced to 1.42 to 1.25, and is now, as has been seen by Dr. Lardner's experiments, reduced to one-third, or even to one-fourth pound per ton per mile.

By the exposure of the cylinders in the Rocket, and engines of a similar form, to the atmosphere, a great waste of heat was incurred, and it was accordingly determined to remove them from the exterior of the boiler, and to place them within a casing immediately under the chimney; this chamber was necessarily kept warm by its proximity to the end of the boiler, but more by the current of heated air which constantly rushes into it from the tubes. This change also rendered another necessary, which fortunately likewise tended to improve the working of the engines. In the former engines the piston rods were connected with one of the spokes of the wheel as a crank, outside the carriage; this, however, was now impracticable; at least it was found more convenient to connect the piston rods of horizontal cylinders by cranks at right angles to each other, on the axles of the great wheels. By this means it was found that the working of the Machine was more equable, and productive of less strain than in the former arrangement. One inconvenience, however, followed, that the bent axle to form the crank was much more liable to accident; to prevent which, much greater thickness and weight are necessarily employed, and even with these some fractures have ensued.

In the more recent engines two safety valves are introduced, one of them locked up from the engine man. The tubes are smaller and more numerous than in the early engines, and the heat is more completely extracted from the air before it enters the chimney, and other modifications are being constantly introduced, preserving, however, at the same time, the general principle of the first construction, which may be thus enumerated.

Machinery

Manufactures.

Pl. xxi.
Fig. 7.

First, the great power of draught in the furnace, by projecting the waste steam into the chimney; second, the great abstraction of heat from the air, by its passage through the tubes, traversing the boiler; and third, which is however a new principle of working, keeping the cylinders warm by immersing them in the chamber under the chimney. These principles, pushed to a greater extent in almost every new engine, have greatly improved the locomotive engine, and there can be no doubt that much more will still be effected. In plate xxi. fig. 7, is represented one of the most approved railway engines. A is the cylindrical boiler, the lower half of which is traversed by small tubes, as already described; these are usually from eighty to one hundred in number, about one and a half inch in diameter; the boiler is seven feet long; the fire chamber is affixed to one end of it at F, and the other end is immediately under the chimney. The piston rods are supported in a horizontal position by guides, and connecting rods extend from them, under the engine, to two cranks placed on the axle of the large wheels. The effects of inequalities in the road are counteracted by springs, being below the axle of the great wheels, and above that of the less. The steam is supplied to the cylinder, and withdrawn by means of the common sliding valves, which are worked by an eccentric placed on the axle of the great wheels of the carriage. The motion is communicated from this eccentric to the valve by sliding rods. The stand is placed for the attendant at the end of the engine, next the fire-place F, and two levers, L, L, project from the end, which communicate with the valves by means of the rods, by which the engine is governed, to stop or reverse the motion. The wheels of these engines were at first constructed of wood with strong iron tires and flanges, but recently iron wheels have been introduced with hollow iron spokes. The hinder carriage is drawn by the engine as usual, containing fuel and water; and when the load is of a medium weight, the engines perform the journey from Liverpool to Manchester without a fresh supply of water; but when the load is heavy, a supply of water is taken in at the usual station in the middle of the journey.

Concluding remarks.

(313.) We may here bring to a conclusion our description of locomotive Railway engines, and after the several remarks interspersed in the different divisions of the subject, we have but few to make in this place. We have traced the engine through its successive grades, and have shown a general advance of it towards perfection. We have seen a reduction of fuel of more than one thousand per cent. with an increase of speed, if not in the same ratio, of a very considerable amount; and we cannot but still anticipate further ameliorations. At present the enormous wear and tear of the engine is the great drawback upon the many other advantages such works possess; and we cannot but hope that practice will lead to a great alteration in this respect. The speed, perhaps, hitherto aimed at is unnecessarily great; and if this were diminished, the power of the engine, and the intensity of the fire, need not be pushed to the same extent, which would, no doubt, contribute very largely towards a reduction of expenditure. In all future Railways, it ought also to be a great object to obtain as level a road as possible, even at a great expense in the first outlay. In the rail we have described, the greatest rise is one in ninety-six, but even this renders the power necessary to ascend it nearly three times as great as that which will draw the load along a horizontal plane. The

resistance on a good rail, we have seen, is about $\frac{1}{180}$ th of the load, whereas to ascend a plane of $\frac{1}{96}$, a ninety-sixth part of it has to be actually lifted, making the whole force required as above stated nearly three times what is requisite on the plane, and if such force cannot be employed, the load must either move slower or be helped up by an additional engine. There is great danger also, if the power is sufficient to take the load up the plane without assistance, that the friction on the rail will be inadequate to the action, and if it is sufficient for this, it is undoubtedly much too great, or more than is requisite, for the plane. All inclinations are, therefore, very injurious to Railway carriages, and ought, as above stated, to be as far as possible avoided, even at a great increase in the first expense. Another object, or one which, indeed, may be said to be involved in the former, is to keep the locomotive carriage as light as can be, with reference to the amount of resistance it has to overcome; for we have seen in the experiments on Railways, given in the early part of this Essay, that heavy loads cause a resistance much more than is proportionate to the weight, and which is accounted for by such condensed pressures deflecting the rail as they pass along, thereby always producing an effect similar to that of drawing a carriage up an inclined plane; this is a point, however, on which we will not insist, because it is one, no doubt, which has attracted the attention of the Directors of the Liverpool rail, and they have rather increased than diminished the weights of their engines, and the loads they have to draw, from the commencement to the present time. Of course the attendance on one large engine costs less than for two others, each of half the weight and power, and probably the first cost of the one is also less than that of the other two, which may, in some measure, balance the evil above mentioned. Practice, however, will settle all these points, and ultimately establish rules and principles of working, highly valuable to future directors of such works.

In writing the above account, we have availed ourselves of the labours of several authors, which it was not thought necessary to particularize as we proceeded. Besides the Parliamentary Report of the Committee on the Liverpool and Manchester Railway, and the Report of the Commissioners for the Holyhead roads, we have been much indebted to Mr. Booth's Report. To the Works on Railways by Tredgold, Wood, Gray, and Palmer, to Dr. Lardner's Lectures on the Steam Engine, and to various Periodical Journals, amongst which we ought to mention the *Mechanics' Magazine*, whose Editor throughout has directed his particular attention to the progress of the Work last described. The *Journal of Elemental Locomotion*, and Mr. Gordon's *Treatise on Locomotive Engines* have also been occasionally consulted, but the latter two more particularly for the following Section.

Application of Locomotive Engines to common Roads.

(314.) It remains for us to notice the progress which has been made in the application of locomotive engines on common turnpike roads. The employment of these engines on Railways may be said to be fully established, although the practice may not yet have arrived at perfection; but their application to common roads is certainly in its infancy, much still remaining to be effected, although a great deal has been done; indeed quite sufficient to prove that the object is practicable and attainable by

Machinery

Application of locomotives to common roads.

Manufac-
tures.

perseverance. Already journeys have been made to Bath, Southampton, Stratford on Avon, and to other places. Steam coaches have made the regular journeys between one town and another, like common Stages, for months in succession; but private interest and popular prejudices have too frequently interfered with the progress, and prevented the continuance. A Society is, however, now in progress of being formed, with one of our most distinguished engineers to direct its proceedings, whose object is the general establishment of these carriages, on several of the most frequented roads in the Kingdom, while Parliament has interfered to protect the ingenious speculator from the impositions to which they have been too often exposed by certain turnpike trusts.

The history of this practice is recent, and confined to a short period, and cannot be better given than in the precise words of the Report of a Committee of the House of Commons, appointed to inquire into, and report upon the proportion of tolls which ought to be imposed upon coaches and other vehicles propelled by steam or gas upon turnpike roads; and also, to inquire into, and to report upon, the rate of toll actually levied upon such coaches or other vehicles under any Acts of Parliament now in force; and who were instructed to inquire generally into the present state and future prospects of land carriage, by means of wheeled vehicles, propelled by steam or gas on common roads, and to report upon the probable utility which the Public may derive therefrom; and who were empowered to report the minutes of the evidence taken before them to the House. This Committee having examined the matters referred to them, agreed to the following Report.

Parlia-
mentary
Report on
the applica-
tion of loco-
motives to
common
roads.

(315.) "The Committee proceeded in the first instance to inquire how far the science of propelling carriages on common roads, by means of steam or mechanical power, had been carried into practical operation; and whether the result of the experiments already made had been sufficiently favourable to justify their recommending to the House that protection should be extended to this mode of conveyance, should the tolls imposed on steam carriages by local Acts of Parliament be found prohibitory or excessive.

"In the progress of their inquiry, they have extended their examination to the following points, on which the chief objections to this application of steam have been founded; viz. the insecurity of carriages so propelled, from the chance of explosion of the boiler, and the annoyance caused to travellers on public roads, by the peculiar noise of the Machinery, and by the escape of smoke and waste steam, which were supposed to be inseparable accompaniments.

"It being also in charge to the Committee, to report upon the proportion of tolls which should be imposed upon steam carriages, they have examined several proprietors of those already in use, as to the effect produced on the surface of roads by the action of the propelling wheels.

"As this was too important a branch of their inquiry, to rest entirely on the evidence of individuals, whose personal interest might have biassed their opinions, the Committee also examined several very scientific engineers, by whose observations on the causes of the ordinary wear of roads, they have been greatly assisted.

"The Committee were directed also to report on the probable utility which the Public may derive from the use of steam carriages. On this point they have examined a Member of the Committee, well known for his

intelligence and research on subjects connected with Machinery. the interests of Society, and they feel that they cannot fulfil this part of their instructions better than by merely referring the House to the evidence of Colonel Torrens.

"These inquiries have led the Committee to believe that the substitution of inanimate for animal power, in draught on common roads, is one of the most important improvements in the means of internal communication ever introduced. Its practicability they consider to have been fully established; its general adoption will take place more or less rapidly, in proportion as the attention of scientific men shall be drawn by public encouragement to further improvement.

"Many circumstances, however, must retard the general introduction of steam as a substitute for horse power on roads. One very formidable obstacle will arise from the prejudices which always beset a new invention, especially one which will at first appear detrimental to the interests of so many individuals. This difficulty can only be surmounted by a long course of successful, though probably unprofitable, experiments. The great expense of the engines must retard the progress of such experiments. The projectors will, for a long period, work with caution, fearing not only the expense incurred by failure, but also that too sudden an exposure of their success would attract the attention of rivals. It is difficult to exemplify to the House, how small and apparently unimportant an adaption of the parts of the Machinery, or of the mode of generating or applying the steam, may be the cause of the most rapid success; yet he who by a long course of experiment shall have first reached this point, may be unable to conceal the improvement, and others will at once reap the benefit of it.

"The Committee are convinced, that the real merits of this invention are such, that it may be safely left to contend with these and similar difficulties; there are others, however, from which the Legislature can alone relieve it. Tolls to an amount which would utterly prohibit the introduction of steam carriages, have been imposed on some roads; on others, the trustees have adopted modes of apportioning the charge, which would be found, if not absolutely prohibitory, at least to place such carriages in a very unfair position, as compared with ordinary coaches.

"Two causes may be assigned for the imposition of such excessive tolls upon steam carriages. The first a determination on the part of the trustees to obstruct, as much as possible, the use of steam as a propelling power; the second, and probably the more frequent, has been a misapprehension of their weight and effect on roads. Either cause appears to the Committee a sufficient justification for their recommending to the House, that legislative protection should be extended to steam carriages, with the least possible delay.

"It appears from the evidence, that the first extensive trial of steam as an agent in draught on common roads, was that by Mr. Gurney, in 1829, who travelled from London to Bath and back in his steam carriage. He states, that although a part of the Machinery which brings both the propelling wheels into action, when the full power of the engine is required, was broken at the onset, yet that on his return he performed the last eighty-four miles, from Melksham to Cranford Bridge, in ten hours, including stoppages. Mr. Gurney has given to the Committee very full details of the form and power of his engine, which will be found in the evidence.

Manufac-
tures.

"The Committee have also examined Messrs. Summers and Ogle, Mr. Hancock, and Mr. Stone, whose steam carriages have been in daily use for some months past on common roads. It is very satisfactory to find, that although the boilers of several engines described, vary most materially in form, yet that each has been found fully to answer the expectation of its inventor; so well in fact have their experiments succeeded, that in each case, where the proprietors have ceased to use them, it has only been for the purpose of constructing more perfect carriages, in order to engage more extensively in the business."

"When we consider that these trials have been made under the most unfavourable circumstances, at great expense, in total uncertainty, without any of those guides which experience has given to other branches of engineering; that those engaged in making them are persons looking solely to their own interests, and not theorists attempting the perfection of ingenious modes; when we find them convinced, after long experience, that they are now introducing such a mode of conveyance as shall tempt the Public by its superior advantages from the use of the admirable lines of coaches which have been generally established; it surely cannot be contended that the introduction of steam carriages on common roads is merely an uncertain experiment unworthy of legislative attention."

"Besides the carriages already described, Mr. Gurney has been informed, that from twenty to forty others are being built by different persons, all of which have been occasioned by this decided journey in 1829."

"The Committee have great pleasure in calling the attention of the house to the evidence of Mr. Farey. His opinions are the more valuable from his uniting, in so great a degree, scientific knowledge to a practical acquaintance with the subject under consideration. He states, that he 'has no doubt whatever, but that a steady perseverance in such trials will lead to the general adoption of steam carriages;' and again, 'that what has been done proves to his satisfaction the practicability of propelling Stage coaches (by steam) on good common roads, in tolerably level parts of the country, without horses, at a speed of eight or ten miles per hour.'

"Much of course must remain to be done in improving their efficiency, yet Mr. Gurney states, 'that he has kept up steadily the rate of twelve miles per hour; that the extreme rate at which he has run is between twenty and thirty miles an hour.'

"Mr. Hancock 'reckons that with his carriage he could keep up a speed of ten miles per hour without injury to the Machine.'

"Mr. Ogle states, 'that his experimental carriage went from London to Southampton, in some places at a velocity of from thirty-two to thirty-five miles an hour.'

"That they have ascended a hill, rising one in six, at sixteen and a half miles an hour, and four miles of the London road at the rate of twenty-four and a half miles per hour, loaded with people."

"That his engine is capable of carrying three tons weight in addition to its own."

"Mr. Summers adds, 'that they have travelled in the carriage at the rate of fifteen miles per hour, with nineteen persons in the carriage, up a hill one in twelve.'

"That he has continued for four and a half miles to travel at the rate of thirty miles per hour."

"That he has found no difficulty in travelling over the worst and most hilly roads."

Machinery

"Mr. James Stone states, 'that thirty-six persons have been carried in one steam carriage. That the engine drew five times its own weight, nearly at the rate of from five to six miles per hour, partly up an inclination.'

"The several witnesses have estimated the probable saving of expense to the Public from the substitution of steam power for that of horses at from one-half to two-thirds. Mr. Farey gives, as his opinion, 'that steam coaches will very soon after their first establishment be run for one-third of the cost of the present Stage coaches.'

"Perhaps one of the principal advantages resulting from the use of steam will be its being employed as cheaply at a quick as at a slow rate; this is one of the advantages over horse labour, which becomes more and more expensive as the speed is increased. There is every reason to expect, that in the end the rate of travelling by steam will be much quicker than the utmost speed of travelling by horses; in short, the safety to travellers will become the limit to speed. In horse draught the opposite result takes place: in all cases horses lose power of draught in a much greater proportion than they gain speed, and hence the work they do becomes more expensive as they go quicker. On this and other points referred to in the Report, the Committee have great pleasure in drawing the attention of the House to the valuable evidence of Mr. Davies Gilbert."

"Without increase of cost, then, we shall obtain a power which will insure a rapidity of internal communication far beyond the utmost speed of horses in draught; and although the performance of these carriages may not have hitherto attained this point, when once it has been established that at equal speed we can use steam more cheaply in draught than horses, we may fairly anticipate that every day's increased experience in the management of the engines will induce greater skill, greater confidence, and greater speed."

"The cheapness of the conveyance will probably for some time be a secondary consideration. If at present it can be used as cheaply as horse power, the competition with the former modes of conveyance will first take place as to speed. When once the superiority of steam carriages shall have been fully established, competition will induce economy in the cost of working them. The evidence, however, of Mr. M'Neil, showing the greater efficiency with diminished expenditure of fuel by locomotive engines on Railways, convinces the Committee, that experience will soon teach a better construction of the engines, and a less costly mode of generating the requisite supply of steam."

"Nor are the advantages of steam power confined to the greater velocity attained, or to its greater cheapness than horse draught. In the latter, danger is increased in as large a proportion as expense, by greater speed. In steam power, on the contrary, there is no danger of being run away with, and that of being overturned is greatly diminished. It is difficult to control four such horses as are able to draw a heavy carriage ten miles per hour, in case they are frightened, or choose to run away; and for quick travelling they must be kept in that state of courage, that they are always inclined for running away, particularly down hills, and at sharp turns of the road. In steam, however, there is little corresponding danger, being perfectly controllable, and capable of exerting its power in reverse in going down hills. Every witness examined has given the fullest

Manufac-
tures.

and most satisfactory evidence of the perfect control which the conductor has over the movement of the carriage. With the slightest exertion it can be stopped or turned, under circumstances where horses would be totally unmanageable.

"The Committee have, throughout their examinations, been most anxious to ascertain whether the apprehension very commonly entertained, that an extensive use of these carriages on roads would be the cause of frequent accidents and continued annoyance to the Public, were well founded.

"The danger arising from the use of steam carriages was stated to be twofold: that by which passengers are exposed from explosion of the boiler and the breaking of the Machinery; and the effect produced on horses by the noise and appearance of the engine.

"Steam has been applied as a power in draught in two ways: in the one, both passengers and engine are placed on the same carriage; in the other, the engine carriage is merely used to draw the carriage in which the load is conveyed. In either case, the probability of danger from explosion has been rendered infinitely small, from the judicious construction of the boiler which has been adopted.

"These boilers expose a very considerable surface to the fire, and steam is generated with the greatest rapidity. From their peculiar form, the requisite supply of steam depends on its continued and rapid formation; no large and dangerous quantity can at any time be collected. Should the safety valve be stopped, and the supply of steam be kept up in greater abundance than the engines require, explosion may take place, but the danger would be comparatively trifling, from the small quantity of steam which could act on any one portion of the boilers. As an engine invented by Mr. Trevethick has not been as yet applied to carriages, the Committee can do no more than draw the attention of the House to the ingenuity of its contrivance. Should it in practice be found to answer its expectation, it will remove entirely all danger from explosion. In each of the carriages described to the Committee, the boilers have been proved to a considerably greater pressure than they can ever have to sustain.

"Mr. Farey considers that the danger of explosion is less than the danger attendant on the use of horses in draught; that the danger in these boilers is less than in those employed on the Railway, although there even the instances of explosion have been very rare. The danger arising to passengers from the breaking of the Machinery needs scarcely to be taken into consideration; it is a mere question of delay, and can scarcely exceed in frequency the casualties which may occur with horses.

"It has been frequently urged against these carriages that wherever they shall be introduced, they must effectually prevent all other travelling on the road, as no horse will bear quietly the noise and smoke of the engine.

"The Committee believe that these statements are unfounded. Whatever noise may be complained of, arises from the present defective construction of the Machinery, and will be corrected as the makers of such carriages gain greater experience. Admitting even that the present engines do work with some noise, the effect on horses has been greatly exaggerated. All the witnesses accustomed to travel in these carriages, even on the crowded roads adjacent to the metropolis, have stated,

that horses are very seldom frightened in passing. Mr. Machinery Farey and Mr. M'Neil have given even more favourable evidence, in respect to the little annoyance they create.

"No smoke need arise from such engines. Coke is usually burned in locomotive engines on Railways to obviate this annoyance; and those steam carriages which have been hitherto established also burn it. Their liability to be indicted as nuisances will sufficiently check their using any offensive fuel.

"There is no reason to fear that steam will cause much annoyance. In Mr. Hancock's engine, it passes into the fire; and in other locomotive engines it is used in aid of the power, by creating a quicker draught, and more rapid combustion of the fuel. In Mr. Trevethick's engine it will be returned into the boiler.

"The Committee not having received evidence that gas has been practically employed in propelling carriages on common roads, have not considered it expedient to inquire as to the progress made by several very scientific persons, who are engaged in making experiments on gases, with the view of procuring a still cheaper and more efficient power than steam.

"The Committee having satisfied themselves that steam has been successfully adopted as a substitute for horse power on roads, proceeded to examine whether tolls had been imposed on carriages thus propelled, so excessive as to require legislative interference; and also to consider the rate of tolls by which steam carriages should be brought to contribute, in fair proportion with other carriages, to the maintenance of the roads on which they may be used.

"They have annexed a list of those local Acts in which tolls have been placed on steam, or mechanically-propelled carriages.

"Mr. Gurney has given the following specimens of the oppressive rates of tolls adopted in several of these Acts. On the Liverpool and Prescott roads, Mr. Gurney's carriage would be charged £2. 8s., while a loaded Stage coach pays only 4s. On the Bathgate road, the same carriage would be charged £1. 7s. 1d., while a coach drawn by four horses would pay 5s. On the Ashburnham and Totness road, Mr. Gurney would have to pay £2, while a coach drawn by four horses would be charged only 3s. On the Teignmouth and Dawlish roads, the proportion is 12s. to 2s., which exorbitant tolls on steam carriages can only be justified on the following grounds.

"First, because the number of passengers conveyed on or by a steam carriage will be so great as to diminish (at least to the extent of the difference of the rate of toll) the total number of carriages used on the road; or, secondly, because steam carriages induce additional expense in the repairs of the road.

"The Committee see no reason to suppose that, for the present, the substitution of steam carriages, conveying a greater number of persons than common coaches, will take place to any very material extent; and as to the second cause of increased charge, the trustees, in framing their tolls, have probably not minutely calculated the amount of injury likely to arise from them.

"The Committee are of opinion, that the only ground on which a fair claim to toll can be made, on any public road, is to raise a fund, which, with the strictest economy, shall be just sufficient, first, to pay the expense of its original formation; secondly, to maintain it in good and sufficient repair.

"Although the Committee anticipate that the time is

Manufac-
tures.

not far distant, when, in framing a scheme of toll for steam carriages, their general adoption, and the great number of passengers which will be conveyed on a small number of vehicles, will render it necessary, not only to consider the amount of injury actually done to the road, but also the amount of the debt which may have been incurred for its formation or maintenance; yet at present they feel justified, by the limited number of such carriages, and by the great difficulties they will have to encounter, in recommending to the House, that, in adopting a system of toll, the proportion of wear and tear of roads by steam, as compared with other carriages, should alone be taken into consideration.

"Unless an experiment were instituted on two roads, the one reserved solely for the use of steam coaches, the other for carriages drawn by horses, for the purpose of ascertaining accurately the relative wear of each, it would be quite impossible to fix, with certainty, the proportion of tolls to which, on the same road, each class of vehicles should be liable. To approximate, however, as nearly as possible to the standard of relative wear, the Committee have compared the weights of steam carriages with those of loaded vans and Stage coaches. They have tried to ascertain the causes of the wear of roads; also the proportion of injury done by the feet of horses and the wheels of coaches; how far that injury is increased by increased velocity; and also in what degree the wear of the roads by loaded carriages may be decreased by any particular form of wheel.

"The Committee would direct the attention of the House especially to the evidence of Mr. M'Neil, whose observations on this branch of the subject being founded on a long course of very accurate experiments, are peculiarly interesting and useful. He estimates that the feet of horses, drawing a fast coach, are more injurious to the road than the wheels, in the proportion of three to one nearly; that this proportion will increase with the velocity; that by increasing the breadth of the tires of the wheels, the injury done to roads by great weights may be counteracted. He considers that, on a good road, one ton may be safely carried on each inch of width of tire of the wheels.

"Mr. M'Adam and Mr. Telford have given corresponding evidence, as to the greater wear caused by horses' feet than by wheels of carriages.

"Each of the above witnesses agrees, that, adding the weight of the horses to that of the coach, and comparing the injury done to a road by a steam carriage of a weight equal to that of the coach and horses, (the wheels being of a proper width of tire,) the deterioration of the road will be much less by the steam carriage than by the coach and horses.

"As to the injury to roads, which is anticipated from the slipping of the wheels, it may safely be left to the proprietors to correct; the action of the wheels slipping, involves a waste of power, and a useless expenditure of fuel, which, for their own sakes, they will avoid.

"Apprehension has also been entertained, that, although the peculiar action of the wheels may not be injurious, yet that, from the great power which may be applied, if the steam were worked at very high pressure, or if the size of the engine were increased, greater weight might be carried than the strength of the road could bear.

"Undoubtedly, in proportion to the advance of the Science, will be the increase of weight drawn by an engine with a given expenditure of fuel; but there are

many practical difficulties to be surmounted, before the weight so drawn can reach the point, when it would be destructive of roads. There are no theoretical reasons against the extension of the size of the engines. The difficulties, according to Mr. Gurney, are of a practical nature, and only in the difficulty of management of a large engine. In proportion as we augment the power of the engines, we must increase their strength, and, consequently, their weight; the greater weight will be a material diminution of their efficacy. To a certain extent, the power may be increased in a greater ratio than the weight; but, with our limited knowledge of the application of steam, and with the present formation of the public roads, the point will be very soon attained, when the advantage of increased power will be counterbalanced by the difficulties attendant on the increased weight of the engines.

"The weight of the steam carriages at present in use varies from fifty-three to eighty hundred weight; but it must be recollected that they are mere models; they were made with attention to strength only, to bear the uncertain strain to which they would be exposed in the course of experiments, and a very considerable diminution of weight may be anticipated.

"The weight drawn, at the rate of ten miles per hour, by Mr. Gurney's engine, has not, on any extent of road, exceeded the weight of the drawing carriage; nor is it likely, with the difficulties to be encountered on the present lines of road, from the quality of the numerous ascents, that the weight drawn will be in excess of the strength of the roads. The immense quantity of spare power required to surmount the different degrees of resistance likely to occur, would render the engine too unmanageable. This will appear evident from the force of traction required to draw a waggon over the Holyhead and Shrewsbury road, which varies from forty to upwards of three hundred pounds.

In considering the effect on roads, we must not overlook one peculiarity, in which they have a great advantage over other carriages. In coaches drawn by horses, the power being without the Machine to be moved, it becomes an object of the greatest importance to give as much effect as possible to the power by diminishing the resistance arising from the friction of the wheels upon the surface of the road. For this purpose, the proprietors of coaches and waggons have adopted every possible contrivance so to reduce the tires of their wheels, that a very small portion of them may press on the road; in some coaches they are made circular in their cross section, so that the entire weight of the carriage presses on a mere point. Should the materials be soft, such wheels cut their way into the road like a sharp instrument. The owners of waggons, too, have adopted a similar plan: Mr. M'Neil states, that the actual bearing part of the tire of apparently broad wheel waggons, is reduced to three inches, by the contrivance of one band of the tire projecting beyond the others.

"With steam, on the contrary, a certain amount of adhesion to the roads is required to give effect to the action of the Machinery, or the wheels would slip round, and make no progress. It appears of little importance, therefore, so far as relates to the engine, whether the requisite amount of friction be spread over a broad surface of tire, or be concentrated to a small point; but as the wheels, by being too narrow, would have a tendency to bury themselves in every soft or newly made road, and thus raise a perpetual resistance to their own pro-

Machinery.

Manufac-
tures.

gress, it actually becomes an advantage to adopt that form which is least injurious to the road. The proprietors who have been examined on this point seem to be quite indifferent as to the breadth of tire they may be required to use.

"These considerations have convinced the Committee that the tolls enforced on steam carriages have, in general, far exceeded the rate which their injuriousness to roads, in comparison with other carriages, would warrant; they have found, however, considerable difficulty in framing a scale of tolls applicable to all roads, in lieu of those authorized by several local Acts.

"With this view, they have carefully examined the various modes of imposing tolls, either suggested by the witnesses, or already adopted.

"They are as follows:

"1. To place a toll proportioned to the weight of the carriage and load.

"2. On the number of passengers.

"3. On the horse power of the engine.

"4. On the number of wheels.

"5. On unvarying toll.

"Each of these plans seems liable to serious objections, which the Committee beg to submit to the House.

"No plan of toll has been more frequently recommended than that of a charge in proportion to the weight of the engine and load. As this is the most plausible, and (if it could be levied without other disadvantages) would probably be the fairest standard, the Committee have considered it right to state, at some length, their reasons for not recommending its adoption.

"If weight be taken as the standard, the toll must be a fixed charge, either upon the weight of the engine and carriage, without reference to the load; or, upon an estimated average of the load carried; or, a fluctuating charge, according to the weight at the several periods of a journey.

"The first would be at least free from the uncertainty of the other two, and therefore would be preferable; but what scale of charge per hundred weight could the Committee recommend as applicable to all roads? Their toll should vary according to every different rate of charge on carriages; besides, it would appear to the trustees very unjust to exclude the consideration of that which would be deemed the most material cause of the wear of their roads; viz. the load.

"A fluctuating charge on weight would be most injurious to a carriage, which will mainly depend for success on its speed; constant altercations would take place between the toll collectors and proprietors; a minute calculation would be required at every turnpike-gate; in fact, unless an accountant were placed at each, the Committee cannot conceive how the proportions could be satisfactorily arranged; nor would there be any desire, on the part of the toll collector, to shorten the delay occasioned by these interruptions.

"Mr. Gurney has delivered in a scale of tolls, graduated according to the weight and width of tire of the wheel. As this has been drawn up by a person interested in the success of steam carriages, it might have been expected to be more favourable to them. The Committee, however, have not adopted it, because of the difficulties and interruptions which a fluctuating rate of toll would induce; besides, this scale purports to be intended for a road, where three-pence is charged for a horse drawing and one penny for a horse not drawing; the scale would be inapplicable, therefore, when

the charge was two-pence and one penny, three-pence and three half-pence, four-pence and one and four-pence, and three half-pence, eight-pence, and so on. Again, what standard of weight in relation to horse coaches, could be adopted? The average weight of loaded coaches differs very much on different roads. It has been suggested that a loaded coach, including the weight of four horses, would weigh on an average four tons, and that if six-pence per horse were chargeable to the coach, six-pence per ton should be placed on a steam carriage; this would be unjust, as vans, which frequently weigh upwards of six tons, would only pay two shillings and a steam carriage would pay three shillings. Even if the injury done to the road by each were equal, this would be an unfair toll; but it will appear more evidently unjust if the greater proportionate injury done by the feet of horses drawing, than by the propelling wheels, be taken into consideration.

"The object of every steam coach proprietor will be to attain the greatest possible lightness of Machinery and engines; because thereby he renders his power more efficient for the draught of the remunerating load. To place the toll on the weight of the engine would tend to induce him to decrease the strength of his boiler and Machinery to an extent which might be dangerous to the passengers, and very detrimental to the success of steam travelling, as the Public will easily be led to believe that accidents really occurring from injudicious legislation, were inseparable from the adoption of this power as an agent in propelling carriages.

"The only fair plea for charging tolls on such carriages, in proportion to their weight, is to prevent a load being propelled or carried which would permanently injure the road; within this limit it would be as injudicious to interfere with their progressive efficiency, (which can only result from improvements of the Machinery and the system of generating and applying steam,) as it would be to tax carriages drawn by large and well-bred horses more heavily than such as were drawn by horses in worse condition and of smaller size and power.

"The roads at present have to sustain waggons, weighing at times, with their horses, nearly ten tons; it is in evidence that the breadth of wheels required by various Acts of Parliament is so easily evaded, that it affords no protection to the road. There appears to the Committee no fair reason to suppose, that steam carriages, approaching even to its weight, will be used on any turnpike-road, at least for a very considerable period, during which the increase of weight will be gradual, and will give ample warning to the Legislature when it should interfere.

"To charge a toll according to the number of passengers conveyed is scarcely less objectionable. If a fluctuating toll be intended, it would be as inadmissible as to propose a similar mode of charging for fast coaches, and would be open to all the cavil and interruptions to which a fluctuating toll on weight would be liable. If the toll were fixed according to the number of passengers the carriage were capable of conveying, it would imply the necessity of a license, limiting the number of passengers and cramping the progress of improvement to a Machine, the capabilities of which can only be ascertained slowly, and by continued experiment.

"It must be also recollected, that these carriages will probably have to travel for a long period without passengers, until by their punctuality and safety they shall

Machinery.

Manufactures.

have induced the public to venture in them. Nor is this probability weakened by the immense number of passengers who commenced using the locomotive carriages on the Manchester and Liverpool Railway, immediately after their introduction. These engines were established amongst a population accustomed to Machinery and steam, and therefore not entertaining the same apprehensions of its danger which will require to be surmounted elsewhere.

"The Trustees of the Liverpool and Prescott road have already obtained the sanction of the Legislature to charge the monstrous toll of one shilling and sixpence per horse power, as if it were a national object to prevent the possibility of such engines being used. Besides, they have supplied no standard of their own conception of horse power. Engineers have differed very much in their estimates of this power; there is not, therefore, much probability that the opposite interests of a steam coach proprietor and toll collector would lead to any agreement as to the meaning of the term. But suppose the Legislature were to settle this point, and to arrange that a certain length of stroke and diameter of cylinder should represent a certain power, we still fail to ascertain that which alone it is essential to know, viz. the actual efficiency of the engine. Can we regulate the density of steam at which an engine of a given size should be worked? To be effectual, it would be also necessary to ascertain the quantity of water consumed; and even this check would be inadequate with an engine on Mr. Trevethick's principle. If the toll be left as at present on horse power, it would be the obvious interest of the proprietor to work with the smallest nominal power, but to increase as much as possible the force of his steam, thereby increasing the probability of explosion.

"Some Trustees have placed the toll upon the number of wheels. The Committee would object to this mode of charge, if only because it interferes between the rival modes of steam travelling, and gives a bounty in favour of that in which the engine is placed on the same carriage with the passengers. The opposite plan of separating the engine from the carriage is that which probably the Public will prefer, until the safety of the mode of conveyance shall have been fully ascertained.

"There is still a more serious objection to this mode of charge: it tends to discourage the use of separate carriages; although it must be evident, that if a certain weight be carried, it will be much less injurious to the road when divided over eight wheels, than when carried on four only. On this point the Committee must again refer to Mr. M'Neil's evidence. They cannot, therefore, recommend the House to adopt a scale of toll which shall increase in inverse proportion to the injury done to the road. It will be seen in Mr. M'Adam's evidence, that the toll on steam coaches, imposed by the Metropolitan Road Act, is liable to this objection.

"Some of the local Acts have placed an unvarying toll on steam carriages. This, if moderate, would be unobjectionable; but the Committee could not propose any sum which would adapt itself to the necessary varieties of expense in keeping up different roads, by which the tolls on common carriages have been regulated. A fixed toll has, too, this disadvantage, that light, experimental carriages, or such as are built solely for speed, could be liable to the same toll as steam carriages heavily laden.

"The Committee feel that, however strong their con-

viction may be of the comparatively small injury which properly constructed steam carriages will do to the roads, yet this conviction is founded more on theory, and, perhaps, what may be considered as interested evidence, than practical experience; they would therefore recommend, that the House should not make, at present, any permanent regulations in favour of steam. The experience which will be gained in a very few years, will enable the Legislature to form a more correct judgment of the effect of steam carriages on roads, than can be now made. They therefore recommend, that the tolls imposed on steam carriages by local Acts, where they shall be unfavourable to steam, shall be suspended during *three years*; and that in lieu thereof, the Trustees shall be permitted to charge toll according to the rate to which the Committee have agreed.

"The House will have perceived, in the former part of this Report, that there are two modes of applying steam in lieu of horses in draught: one where the engine and passengers are on the same carriage; the other where the engine is placed on separate wheels, and is merely used to propel or draw the carriage. Although the difference of weight may be in favour of the former mode, yet, as on the latter it is divided over eight wheels instead of four, its small excess cannot justify a larger toll being imposed, as it will be found much less injurious to the roads. The Committee therefore recommend that, in charging tolls, the engine carriage and carriage drawn shall be considered but as one.

"As it is the opinion of all the engineers examined, that the use of narrow wheels has been the great cause of the wear of roads, and that cylindrical wheels, of a certain width of tire, are not only the least injurious, but that in some states of the road they may be even beneficial, the Committee recommend that the wheels of the engine carriage should be required to be cylindrical, and not less than three inches and half width of tire. No proprietor of steam carriages has expressed the slightest fear of any inconvenience or loss from the use of such wheels. Beyond this, the Committee would not recommend interference with the breadth of tire or form of wheels; it should be left to the proprietors freely to select the breadth of tire they shall find most convenient, in proportion to the weight carried.

"The Committee have divided steam carriages (intended for passengers) into two classes, to be subject to different rates of tolls. The first, where the carriage is not plying for hire, or where, if plying for hire, it shall not be calculated for, or carry at any time more than six passengers: the original cost of such Machines, and the expense of working them, will sufficiently protect the roads from any great number of merely experimental carriages; and for the same reason they will not be of a weight or size likely to be injurious. A steam carriage only calculated to convey six passengers will be solely used where great speed is required, and will be so light, as to cause very little wear of the road, probably much less than many carriages drawn by the number of horses which the Committee recommend as the standard of charge for this class. The toll, therefore, proposed to be placed on this class of steam carriages, is that which (on the several roads where they may be used) is charged on a carriage drawn by two horses.

"In the second class, they have placed all other steam carriages, except those travelling at slow rates for goods only. Carriages of this class should pay the same toll as may be charged on a coach drawn by four horses.

Manufac-
tures.

This may at first appear unjust, from the supposed power of steam to draw almost unlimited weight. The Committee have already enumerated the difficulties hitherto encountered in attempting to propel very heavy loads on turnpike roads. They are such as to discourage the expectation that, within any short period of time, the system will have been so perfected as to give rise to inconvenience from this source; should any hereafter be found, it will then be sufficient to remedy the defect. Until a due proportion of the parts of the Machinery shall have been ascertained, the makers of these carriages will vary but cautiously from the models at present in use; their object will be, for some time, the perfecting of them, rather than the uncertain experiment of increasing their size.

"The Committee do not anticipate that, for a considerable period, steam will be used as a propelling power on common roads for heavy waggons. It appears to have been the general opinion of the witnesses, that in proportion as the velocity of travelling by steam on common roads is diminished, the advantages of steam over horse power are lost. The efficiency of horses in draught is rapidly diminished as their speed is increased; while, on the contrary, the weight which could be carried or propelled at any great velocity by steam, could not be more cheaply conveyed, were the speed decreased to that of the slowest waggon.

"As speed, therefore, is the cause of greatly increased expense where horses are used, while with steam it is comparatively unimportant, it is probable that the latter will be chiefly resorted to when rapidity of conveyance is required. Mr. Gurney considers that, under four miles per hour, horses can be used in draught more economically than steam. Should it, however, be deemed profitable to convey heavy goods by steam carriages, the Committee recommend that there should be as little interference as possible with the number of carts employed; as the effect on the surface of roads would be infinitely more injurious if heavy loads were placed on a single cart, than if the same weight were divided over several. The Committee recommend, that where carriages, containing heavy goods alone, are propelled by steam, the weight of the load should be charged, without reference to the number of carts on which it may be carried.

"As a horse is able to draw from twenty to forty hundred weight on common roads, they propose that each twenty hundred weight of load conveyed in or drawn by a steam carriage, should be chargeable at the same rate of toll as one horse drawing a cart.

"A charge on weight is not so objectionable where goods are conveyed at a slow rate, as when speed is alone required.

"In conclusion, the Committee submit the following summary of evidence, given by the several witnesses, as to the progress made in the application of steam to the purposes of draught on common roads.

"Sufficient evidence has been adduced to convince your Committee,

"1. That carriages can be propelled by steam on common roads at an average rate of ten miles per hour.

"2. That at this rate they have conveyed upwards of fourteen passengers.

"3. That their weight, including engines, fuel, water, and attendants, may be under three tons.

"4. That they can ascend and descend hills of considerable inclination with facility and safety.

"5. That they are perfectly safe for passengers.

"6. That they are not (or need not be if properly constructed) nuisances to the Public.

"7. That they will become a speedier and cheaper mode of conveyance than carriages drawn by horses.

"8. That as they admit of greater breadth of tire than other carriages, and as the roads are not acted on so injuriously as by the feet of horses in common draught, such carriages will cause less wear of roads than coaches drawn by horses.

"9. That rates of toll have been imposed on steam carriages, which would prohibit their being used on several lines of road, were such charges permitted to remain unaltered."

(316.) Since the above Report was made, the practice of road locomotives has been persevered in, and with considerable success; but we cannot in this place enter into a minute description of the journeys that have been taken, nor all the changes which these carriages have undergone in the hands of different engineers; but we shall avail ourselves of a very ingenious Work on *Locomotion by means of Steam Carriages on common Roads*, by Alex. Gordon, Civil engineer, to give a description of one of those engines which have made the most successful experiments in this practice. Before entering upon this, however, it may be well to state a few particulars respecting some more early claims to the invention than are referred to in the preceding Report. It appears that Dr. Robison, in 1759, at that time a student at Glasgow, and the celebrated Watt had some faint ideas on the subject of employing steam for producing locomotion; and that this speculation, which was Dr. Robison's, led to the first acquaintance of these two distinguished individuals. It does not appear, however, that any attempts were made beyond mere suggestions.

In 1772, Oliver Evans, an ingenious American, made some experiments on this subject, and continued to make different trials till 1786, when he petitioned the Legislature of Pennsylvania for his exclusive right to use his improvements in flour-mills and steam waggons in that State.

Within this interval, 1784, Mr. Symington of Falkirk projected a locomotive engine for common roads, and made a small model to illustrate the nature of its action; and the inspection of this model, as we have seen in the History of Steam Navigation, induced Mr. Millar to order Mr. Symington to construct for him two engines, on somewhat similar principles, to be applied to steam vessels. In the same year, 1784, Mr. Watt took out a patent, amongst other improvements in the steam engine, for a mode of applying it to wheel carriages. Scarcely any thing, however, resulted from these projections; but in the year 1802, Mr. Trevethick invented a high pressure engine and boiler in one Machine, and made several experiments in and about the metropolis, on its power as a road locomotive, but failed in bringing it to perfection for that purpose. It was afterwards applied as a locomotive on a Railway, at Merthyr Tidvil, as already stated in a preceding page.

In 1821, Mr. Griffiths had a steam carriage constructed by Messrs. Bramah and Sons, which was intended to work on a good turnpike road. It is stated by Mr. Gordon to have been very perfect in all the adaptations of the mechanical parts, and that it failed only from a defective principle in the construction of its boiler.

Machinery

First attempts at working locomotives on roads.

Manufac-
tures.

In 1822, a patent for a locomotive steam carriage was taken out by Mr. David Gordon, and a second in 1824; but in both these the motion was given by propellers, somewhat similar in principle to that of Mr. Brunton, already referred to (Art. 302.)

The use of propellers was, however, at this time found to be unnecessary; and we come now to the time when the locomotive engine for common roads began to assume a more promising character, and to be occasionally exhibited in Public. Passing over the two patents of Messrs. John and Samuel Seaward, and of Messrs. Hill and Burstall, we come to Mr. Gurney, who, in 1825, produced a specimen of this species of engine, which offered so many grounds for hopes of ultimate success, that to him and his unwearied perseverance we are (as stated in the preceding Parliamentary Report) mainly indebted for the progress made in this practice. Without stopping to describe this carriage, we proceed to Mr. Gurney's second patent, in 1827. Under this patent he worked with a steam carriage resembling, in external appearance, a common Stage coach, the boiler being situated in the hind boot; in the front boot a blower, like the revolving fans of a winnowing Machine, moved round horizontally in a close box, from which a tube conveyed the blast to the coal ash-pit of the fire-place, and the hind wheels acted upon the cranks on the hind axle. The hind wheels had sockets or boxes in their centre, like common wheels, so that either of them might be made to run loose on the axle when required, but were fastened to the axle, so as to turn round with it when necessary. This was effected by means of a round plate, fitted on a hexagonal part at each end of the axle, and a similar plate fastened to the nave of each wheel, close to the former; screw bolts passed between the two plates, and, secured with nuts, gave the desired connection, which could again be withdrawn by removing the bolts.

Description
of boiler.
Pl. xxii.
Fig. 4, 5, 6.

(317.) But the great advantage which Mr. Gurney's contrivance has over others, consists in his boilers. This may be described as follows: pl. xxii. fig. 4, shows a section of one of these boilers; *a* is the point at which the water is pumped into the boiler; *b* the water level in the separator *E*. It will be observed that *A*, *B*, *C*, *D*, fig. 4, 5, 6, are all full of water. The fire is made at *F*, and plays through, around, and between these tubes. The hotter particles of water occasion a continuous flow from *A* through *C* to *D*; when they arrive at *D*, the colder particles descend through *B*, and again are drawn through the tubes *C*. These tubes, it will be seen, by their inclination, always offer an ascent for the hot particles and for the steam. By this arrangement the circulation is constant and complete, and the steam is rapidly given off at *E*, where it is ready for the engine. The chamber *E* is sometimes placed vertically, instead of horizontally; sometimes, also, there are two of these steam chambers *E* connected together, and to the engine; *G* is the fire door, and *H* the flue.

In the later coaches of the patentee's construction, he has discontinued a blast for urging the fire, and has used the waste steam to occasion the draught as described in (Art. 212.) This is effected by blowing the waste steam by several small jets upwards into the lower part of the chimney. The increase or decrease of draught is regulated by the size of the aperture through which is ejected. A very perfect draught is thus obtained, and the fire can be enlivened or damped according to the required speed of the engine. With a boiler containing

so small a quantity of water, and so large a proportion of heating surface, the facility of lessening or increasing the heat, and, consequently, the power of the steam, is very great; and this facility is highly important for economizing the fuel, and for the quick and certain management of the steam carriage on hilly or crowded roads.

Machinery

In 1831, Mr. Gurney having completed three carriages for Sir Charles Dance, that gentleman commenced running one of them regularly on the road between Gloucester and Cheltenham, and continued so to do constantly and successfully four months; until tired of the opposition and imposition of the turnpike trusts, he withdrew his carriage, and, at his suggestion, Mr. Gurney presented his Petition to Parliament on the subject of these tolls, which led to the appointment of the Committee, and the Report which we have given in a preceding page.

(318.) We have, as above stated, been indebted to Mr. Gordon for many of the preceding particulars; and from the same authority we have obtained the following description of one of the latest and most improved of Mr. Gurney's carriages. This is shown in the plate already referred to, fig. 1, 2, 3. *A* is the position of the boiler above described; *B* the steam pipe which passes under the body from the boiler, till it arrives at the point *N*, and from thence passes down to the valve boxes *CC*, of the cylinders *DD*; *NN* are fixed points, on which the body rises and falls, as on a hinge, when the spring above the hind axle has play. If the steam pipes were not brought close to this point, they could not be kept tight, as the play of the spring would disturb them, and occasion a leakage. *E* is the wheel of the parallel motion, which runs horizontally between the parallel bars *GG*. Through this wheel there is a spindle or axle, upon the ends of which a forked or double connecting rod *F* is attached, so that in the revolution of the crank *K* the parallel bars are inside the double connecting rod *F*. This is shown more distinctly in the plan, fig. 3, which exhibits the two engines at different parts of their stroke. At *H* is placed the water pump, each engine having a separate one; and each pump is worked by its connection with the piston rod of its corresponding engine. The valve motion is obtained from eccentrics on the crank shafts, outside the cranks. The valve rods will be easily distinguished at *mm*: at the extreme ends of the crank shafts, *i. e.* the hind axle of the drag, and between the spring and the wheel on each side, is shown the driving arm, marked *PP*, by means of which the power is conveyed from the crank shaft to the circumference of the hind wheel, so that one or both wheels may be used. It will be seen that the driving arm in the section being pressed up by the engine against the bolt, which is shown above it, must force the wheel in that direction, and thus propel the carriage forward, the friction or adhesion of the wheel on the ground serving as a fulcrum to the power. One or both of the hind wheels are thus used as occasion requires, for it is obvious if the bolt be withdrawn, the driving arm *P* will revolve without propelling the wheel; but as it is found in practice, that one wheel is sufficient for taking the carriage even up hill, the provision of the driving arm is seldom had recourse to. The part seen at *J* in the three figures will sufficiently explain how the carriage is turned. The pinion on the lower end of the rod *J* works in a rack, which is made fast to the front axletree, so that if the conductor, who sits on the box, turn the wheel (on

Description
of Mr. Gur-
ney's car-
riage.

Pl. xxii.
Fig. 1, 2, 3.

Manufac-
tures.

which his hand rests) to the right, the pinion will draw the rack round also to the right, and with it the front wheels, the same as if they were turned by horses, and with equal or greater facility and certainty. On the foot board is placed a lever L, which when pulled up by the conductor reverses the motion of the engines, and thus stops the carriage, or propels it backward if necessary. The body of the carriage is in the shape denominated by coachmakers a brisca; it is entirely used as a drag to another carriage which we may conceive attached at Q. No passengers are allowed to be in the drag; the coach-box being occupied by the conductor, and the interior by the boiler at A, and by the engineer, the fuel and water are at R. Upon the highest point of the steam pipe B B is a handle, which can be turned either by the conductor or by the engineer for the greater or less supply of steam. The chimney is placed in the back of the body, and is so constructed that it cannot be seen by the horses on the road. The water for the boiler is introduced into the tanks through a funnel which resembles a dicky on the hind boot.

When the carriage is to be started, the steam being already got up, the conductor, who sits ready on the box, opens the steam cock by the lever or handle at his side; the steam then finds its way along B B, to the cylinders D D, the action of the engine then commences, and the carriage is urged forward on its proposed journey. We cannot in this place enter into further description of locomotive engines for common roads, although various other principles, both in form and construction, are certainly highly deserving of particular detail; such are the carriages of Mr. Hancock, of Mr. Gibbs, of Messrs. Sommers and Ogle, &c.; but for these we must be content to refer the reader to Mr. Gordon's Treatise already referred to, also to the *Mechanics' Magazine*, which has occupied much space in the description of these vehicles, and to the *Journal of Elemental Locomotion*, devoted almost entirely, as its title imports, to this subject.

SIMPLE AND COMPOUND MACHINES.

Definition
of Engines,
Machines,
Mills, &c.

(319.) In the preceding part of this Treatise we have illustrated the nature of the several first movers, explained the elementary parts of Machinery, and their modes of communication, treated of several classes of mills, so far as regards the means employed to produce a first rotation, and whose denomination is derived from those means, as hand-mill, wind-mill, water-mill, &c., including the steam engine. We have also shown the application of the latter to mining, navigation, and locomotion; but it still remains to treat of the Machines put in motion by the elementary forces and rotations thus obtained. As far as we have hitherto described the wind or water-mill, no ulterior object is involved. The first motion being produced, we may employ it to grind corn, to spin cotton, to pump water, to roll iron, or to effect any other mechanical object; and our business now is, to describe the Machines, both simple and compound, by which those objects are obtained.

In the present state of Arts and Manufactures in this Country, where almost every mechanical process is effected by Machinery, it is difficult to classify the subjects in this division of our Work; and the classification also, necessarily, is somewhat arbitrary. The same construction being sometimes called an Engine, a Machine, or a Mill.

We shall, however, endeavour in this respect to conform as nearly as possible to the common language of the Arts; but if, after all, a Machine should not be found under the head by which it has been commonly known to the reader, we must trouble him to refer to some of the other heads; and sometimes the description of a Machine may be found under that of the Manufactures or Manufactory in which it is employed. Such references, however, will be avoided as much as possible; but it must be obvious, that where the same thing is known by different names in different Counties, and even in the same County or town, it is impossible to avoid them entirely.

With respect to the two terms, Engine and Machine, there is very little if any distinction to be discovered in their original signification; and a mechanical construction has been, therefore, called the one or the other according to the caprice of the inventor; but the term Mill has certainly a more distinct original meaning, denoting a Machine employed in the process of grinding. It afterwards took a more extended signification, *i. e.* any Machine used in crushing or pressing by a rotary motion; such are the sugar-crushing mill, the sugar-cane mill, stamping mill for ores, oil-mills, &c., and lastly, it was applied to nearly every Machine worked either by wind or water as a first mover. This, undoubtedly, arose from confounding the means employed to produce rotation with the operation performed by it. In early times, wherever a water wheel was at work, its business was grinding, and the whole was properly a mill; but as the Arts advanced, the rotation produced by the power of the water was employed for various purposes, and the denomination of mill remained, although in many cases very improperly, as in those of silk-mill, cloth-mill, cotton-mill, &c. These obvious improprieties will be avoided in our classification; but for the rest it is, perhaps, more desirable to arrange the several Machines according to the denomination under which they are generally known, than by a critical distinction as to their proper designation, to confuse the reader by unnecessary references from one head or class to another.

It may also be well to observe, that in treating of some Machines it will be convenient to describe the preparation of the material previous to its entering the same, and the nature and application of its produce; while in others the simple operation only can be illustrated, and the subsequent processes will be treated of under some distinct head of Manufacture. It is hoped, however, that any inconvenience which might thus arise to the reader, will be in a great measure obviated by the copious alphabetical Index given at the end of the volume.

Engines.

(320.) It has been already remarked, that the distinction between what is denominated an Engine, and what is called a Machine, is very arbitrary; unless, indeed, we consider as properly falling under the former class those Machines in which great exactitude of operation is required. Such, for example, as are employed in cutting screws, particularly original screws, dividing mathematical and astronomical instruments, which are, we believe, universally called Engines. But besides these, we have pile-driving Engine, fire Engine, &c., which require no extraordinary accuracy, either in their construction or use; so that, in fact, we must consider the two terms as

Engines.

Manuf-
tures.

implying no kind of distinction except so far as custom has prevailed in appropriating the one or the other to particular mechanical contrivances; and conforming also to custom in this respect, we shall, under this head, describe a few Machines which are more generally spoken of under the designation of Engines.

Cutting Engines.

(321.) Under this head are classed all those Machines employed in cutting various materials into particular figures, or for particular purposes, such as those used in cutting combs, screws, teeth of wheels, files, &c. These, as we have observed above, are sometimes called Engines and sometimes Machines. It is proposed here to describe them under the former designation.

Engine for
cutting
combs.

Engine for cutting combs.—In preparing the material of which combs are formed, some preliminary operations are required, which, however, it is not necessary to describe in this place, as it consists only in sawing the ivory, wood, &c., into their laminæ, either by hand or by a circular saw.

Materials for combs are box-wood, ivory, horn, and tortoise-shell. These being cut into pieces of the proper size, and the general form of the comb having been given to them by common tools, such as rasps, scrapers, &c., the next and most important part of the process is cutting the teeth.

This was formerly done, in all cases, by means of a double saw, consisting of two parallel blades, one of them being deeper than the other, so that when the deepest blade has cut to the whole depth of a tooth, the other shall have cut only to the depth of half a tooth. In using it, the deep blade makes the first cut at a little distance from the outside of the material, so that by the first action of the saw the outer side of one tooth and half the inner side of the same tooth are cut. The saw is then advanced one tooth so that the deep saw rests in the cut made by the shallow saw, while this latter is ready to form half the outside cut of the second tooth. Thus the saw is advanced a tooth at a time, the intervals between the teeth are rendered equal, and half the cut for the deep saw being already made, the tool is prevented from swerving, or cutting teeth of unequal thickness.

Soon after the invention of the circular saw, it was applied to comb cutting, by fixing on one axis two circular saws, one of greater diameter than the other, and regulating the distance between them according to the fineness of the teeth to be cut. Both the straight and circular double saws are now in use; the former being still applied to cutting combs out of all the four above-mentioned materials, the latter being used chiefly for combs of box and of ivory. Boxwood and ivory, subjected to the perpendicular action of a cutter, would break and splinter; but horn and tortoise-shell being of a laminated texture, and capable of being rendered soft and flexible by heat, will yield in this state to the action of a sharp vertical cutter without splintering.

Mr. Rick-
etts's en-
gine.

(322.) About twenty years ago, the principal house in London at that time for the sale of combs had received from abroad some patterns of ornaments, like the spikes and balls of coronets, to be attached to tortoise-shell combs. They gave the order to execute these to an ingenious artist of the name of Ricketts, who contrived a punch, by the successive pressure of which on a thin piece

of warm tortoise-shell, he cut out the pattern, piece by piece. On disengaging the pattern from the other part, he observed to himself, here are two combs cut out of the material for only one.

Improving on this hint, he soon contrived an engine, in which a single cutter descended vertically, being put in motion by a treadle and wheel; the bed on which the tortoise-shell was fastened was notched at the side, and these notches fitted into and corresponded with those of a rack placed parallel with it. After every cut, the bed was moved forward by hand the distance of a single notch, and thus an equal interval between all the cuts was secured. But the form of the tooth of a comb being that of a very long triangle, it was necessary that, as the bed was shifted forward, notch by notch, there should also be an alternate motion given to the bed; this likewise was given by hand: thus the first rude attempt at parting combs, *i. e.* for cutting one set of teeth out of the intervals of another set, was completed.

When the knowledge of this engine began to spread abroad, various contrivances were invented to advance the bed, and give the necessary alternate change in direction by Machinery. In some cases this alternation was given to the bed, in some to the cutter itself.

Previously to this time, however, it had occurred to the original inventor, Mr. Ricketts, that the Machinery necessary to produce this alteration of direction might be dispensed with, by making the cutter double, *i. e.* composed of two blades set obliquely, so as nearly to touch at one end, and the other to be as far apart as the width of a tooth; at the same time the blades made a return at their ends to liberate the extremities of the teeth.

It is evident that, while the cut is making, the material must be stationary, and that in the interval between the rise and descent of the cutter, the bed must have advanced the breadth of a tooth. This was effected in Mr. Ricketts's double cutting engines by working the cutter alone by a treadle, and advancing the bed by a screw, to the end of which a winch was fastened, so that one complete or one half turn gave the necessary advance, a pause being made after each turn or half turn, to bring the bed to a stop while the cutter was in action.

(323.) Mr. Rogers's engine obtains this end without the use of a treadle, by means of a single winch. The axis to which the winch is fixed gives motion to the cutter by means of a crank, and on the axis is a wheel having part of the cogs removed; this wheel takes into a common cog-wheel on the axis of a screw, by the turning of which the bed with the work on it is moved forwards. Hence it is evident, that while the Machinery for raising and lowering the cutter is in constant action, as long as the winch is turned, the screw which gives motion to the bed is still and out of action, during that part of the revolution of the winch in which the cogs of the two wheels are not bearing on each other. By enlarging the space from which the cogs of the second wheel are cut, the interval between one tooth and another is diminished; so that any given distance of teeth may be obtained by putting on to the axis of the screw a wheel with the proper number of cogs.

Mr. Ro-
gers's en-
gine.

The engines for parting combs, in all their modifications, have this advantage, of cutting two sets of teeth out of the same quantity of material as, with the common saw, is sufficient only for one set.

But every scale of tortoise-shell is wedge-shaped at the margin, and, therefore, it is only to the thick pieces

Manufac-
tures.

cut out of the middle part of the scale that this new invention can readily apply, for the wedge-shaped margin is not thick enough for the back of the comb. But on the whole, the advantage as regards tortoise-shell is very great, for the prime cost of rough shell of fine quality is four guineas per pound, a price greater than that of silver.

In many cases, however, the thin edge of a piece of tortoise-shell may be strengthened by soldering it to a thicker or larger piece for a back. This is done by heating the shell, and pressing it at the same time; but much care is required lest the shell be overheated, in which case the lamellar texture is destroyed, and the substance becomes as brittle as glass. In Germany and in France many combs are made, the ornamental part of which is stamped by strong pressure in hot steel dies, and two or more pieces of tortoise-shell are united in the same manner; but the colour of the shell so treated is injured, besides being rendered very brittle.

The best English makers, after smoothing and rasping the two surfaces that are intended to be united, place them between two thin boards, and insert the whole in the chops of a screw press. The press is put for some hours into boiling water, and is tightened from time to time; and thus, by allowing a sufficient time, perfect junction is obtained at a heat so low as not to injure either the colour or texture. We are indebted for the above sketch, and to the following description of a very ingenious engine for this purpose by Mr. Rogers, to the *Transactions of the Society of Arts*, vol. xlvii.

Mr. Rogers's engine, as represented in plate xxiii. fig. 1, shows two combs cut of one piece of shell before they are pulled away from each other. The shell is held on a movable bed, which is caused to move the distance of one tooth each time; two chisels are used together, so that one complete tooth is cut at each move; the chisels or cutters are fixed together, as shown in fig. 2 and 3, with four pins, and filling pieces are placed between, the thickness and taper of which are such as correctly to determine the form of the teeth. From the lower filling piece (which is shown separate in fig. 4) a sharp point descends so as to be level with the edges of the cutter; it cuts the point of the tooth away from the opposite comb; but as this double chisel cuts the tooth of one comb and the space of the opposite one, their wider ends are curved out as at *a a*, fig. 5; by this the advancing side cuts half through the point of the next tooth, and at the second move the following curve cuts through the other half, and leaves that tooth detached. Fig. 6 shows the clamp in which the cutters *a a* are held by the screw and nuts *b b*; and as these cutters have to move up and down correctly in the same place, the clamp is firmly fixed (at the right place) by its binding screw *a* on the bar *c c* of the engine; *e e*, fig. 7, are two adjusting screws, by which the chisel edges are placed correctly parallel with the bed *f f*, on which the shell is laid for cutting; *g* is the fulcrum on which the bar *c c* moves; it is a well-fitted joint, moving without shake, and placed level with the bed *f*; *h* is another joint placed firmly clamped, by its screw *i*, to the front end of the bar *c*; and as here the power is to be applied to pull the cutter *a a* down to the work, these two joints, *g* and *h*, are placed in a line level with the cutting edges on the chisels *a a*; they are both, therefore, at the moment of the cutting, level with the bed *f*; and

this is evidently the best arrangement, for by it the chisels have then no lateral motion and no tendency to tilt aside; nevertheless, to overrule all bias that might occur from unequal sharpness, or from any inequality in the substance that is to be cut, an upright loop or standard, *p*, is firmly secured to the engine; through this loop the bar *c c* passes, and can move up and down in it without any side-shake; this, therefore, guides the bar *c*, and further secures the uprightness and steadiness of the cutter. A link in two halves, and screwed together in the middle for the convenience of putting on, connects the joint *h* with the crank *j*, whose axis extends past *l*, and is supported in three standards *m*, *n*, and *o*; these standards are, for the purpose of adjustment, screwed to the projecting loops *p p p*, which, with the arm *g*, are cast in one piece with the lower bed *g*, so that the chisels are held and pulled with the greatest firmness to the cut. On the further end of the cranked axis *l* is placed a wheel *r*, with only a few teeth left on it at one side; these are so placed as only to engage the wheel *s*, when the crank *j* is up, and has lifted the cutters *a a* from the work; the wheel *s* is fixed on a screw *t*, fig. 8, which moves the bed *f f* precisely like the usual slide-rest; *u* is the standard in whose collar the screw *t* is held, and *v* the screw hole through which it passes; this is united to the dove-tailed slide *w*, on which the bed *f* is mounted; this slide is perforated to make room for the screw *t*. By turning the winch *x* the crank *j* pulls down the cutter *a a* on the tortoise-shell *y*, and cuts one tooth; the crank then lifts up the cutters, and at the same time the few teeth of the wheel *r* engage and carry with it the wheel *s*, and thereby advance the screw *t* a given proportion; the wheel *r* then quits its hold of *s* and the crank, and again brings down the cutters to form a second tooth, and so on till the whole number of teeth are cut; this done, another piece of shell is laid on the bed, and it is cut during the return of the bed by merely turning the winch *x* the contrary way, so that no time is lost.

Having now described the motion of the cutters, and the motion of the shell past them, it is necessary to explain the means of holding the horn or shell to the bed. This apparatus was purposely omitted in fig. 7, and fig. 9, 10 are added to show it: *f f* is the bed, at one side of which an adjustable plate, *z z*, is screwed for the purpose of guiding or securing the shell, to be quickly placed central and parallel; to one end of the bed is joined the double fork *l l*, and at the other end is a similar double fork *2 2*, but quite loose; *3 3* are two slender steel springs or bars; they are bent at each end like hooks, by which they are attached by screws and nuts to the joined forks *l l*, at one end, and to the loose forks *2 2* at the other; these forks keep the two bars parallel, and by them they may be adjusted to any suitable distance apart, which should be as near to the cutters *a a* as may be without touching them. These springing bars being thus joined to the bed *l l*, may be lifted by the other end to place the tortoise-shell under them; then, to keep the end *2 2* down, a wide tooth *4* projects from the middle of the forks *2 2*: it snaps past the flutes of a pendent catch *5*, by which it is retained, and thereby the springs *3 3* are held with any required tightness on the tortoise-shell *y*. The catch *5* is joined at the top to a stud *6*, and is pressed outwards against the tooth *4* by a small spring as shown in fig. 10. Again, it is requisite that the springs *3 3* should always go down

Machinery.

Manufactures.

correctly in the same place, that is, parallel with the bed *f*, otherwise the cutters might come against them and be damaged; therefore, two thin cheeks, 7 7, are attached to the stud 6, between which the wide tooth 4 passes, and is thereby always kept central, and thus prevents any lateral motion of the bars 3 3; when the springs 3 3 are to be lifted up, the catch 5 is pressed from the tooth 4 by a lever 8. The bed *f* is hollow underneath, as shown at 9, in fig. 7 and 10, for the purpose of receiving a heater during the time of cutting, as warmth renders horn or shell soft.

To set the engine for cutting finer or coarser teeth, the wheel *r* is changed for another with fewer or more teeth, and the filling pieces between the cutters are changed for others whose thickness answers to the required tooth; these, when once made, may be marked with the same number as the wheel *r*, to which they correspond. The inside faces of the chisels or cutters *a a* are kept flat and perpendicular, so that the tooth never sticks between them, and the taper for sharpening them is all on the outside. By the simple action of this engine, combs may be cut as fast as the workman can attend to them.

It is requisite, for the convenience of the workman, to cause the bar *c* either to rise up of itself or to keep up when put so; for this purpose it is but to fix the winch handle *x*, as in fig. 8, opposite to the crank *j*, and make it heavy enough always to descend and thereby lift the bar *c*; or a spring may be fixed to an arm *g*, to act against the under side of the bar *c*, with sufficient force to raise it up, or at least to hold it up. Fig. 1 to 6 are half the size; fig. 7, 9, and 10 are one-quarter; and fig. 8 is one-eighth; in this figure are shown three ears, 10, 10, 10; they project from the bottom plate *q* of the engine, and serve to screw it to any suitable bench.

(324.) *Dividing engine*.—As Astronomy has advanced to its present state of perfection, a corresponding degree of accuracy has been rendered necessary in the divisions of astronomical instruments, particularly in the arcs of our large mural and zenith sectors; so also in all quadrants, sectants, &c. used for nautical and astronomical purposes: and many of our instrument-makers have obtained great distinction for the ingenuity they have displayed in this particular branch of their Art. One of the most recent and perhaps the most simple of these engines, is the invention of Mr. Alexander Ross, a highly ingenious instrument-maker of Clerkenwell. This engine was presented to the Society of Arts in 1830, and was so highly approved of by that Body for its accuracy and ingenuity, that its author was rewarded by a presentation of their gold medal and a sum of fifty guineas. An account of the instrument is given in the *Transactions of the Society* for 1831, and to that volume we are indebted for the following description and drawing.

Historical sketch of the art of dividing engines.

Historical sketch of the art of dividing engines.—The first method which we have any correct account of is that by beam compasses; these were employed by Graham, Sisson, and Bird. Graham and Sisson obtained the chord of the arc of sixty degrees from the radius, and completed the number of divisions on the quadrant by bi, tri, and quinquesection. Bird computed the chords of certain arcs, and then completed the number of divisions by continual bisection.

Hook and Roemer practised other methods widely differing from the above and from each other. Hook's method consists in racking the quadrant with an endless

screw. Several trials of this were made at the Greenwich Observatory, but the method was found defective, and was soon abandoned. The method of Roemer was, stepping a fixed distance throughout the whole of his arc, the distance being so proportioned to the radius of the arc, that it was very nearly equal to one of the smaller divisions required; the total length of the arc in this case being disregarded, as any number of divisions were converted into degrees and minutes by a table calculated for the purpose. This method has defects which render it useless, because any error arising from the inclination of the dotted points or the porosity of the metal, is chargeable upon the whole arc, so that no dependence could be placed on the result; for his table supposes the whole arc to be truly divided.

About the time of Bird, the Duc de Chaulnes published a method of dividing by micrometer microscopes and several temporary pieces of brass having divisions upon them. Two microscopes, having cross wires in the foci of their eye-glasses, were fixed to a frame and considered as the points of a pair of beam compasses; these were extended to a diameter of the circle, and two of the temporary pieces of brass were attached to the circle by means of wax underneath the microscopes, so that the divisions bisected the crosses in them; then the circle was moved half round, and, if required, the position of the micrometers and pieces of brass were changed, and the operation repeated until they were diametrically opposite. A cutting point was then placed over one division, and a fixed microscope over the other, so that when any division was brought to bisect the cross in the microscope, the cutting point made one diametrically opposite. By the process of trial and adjustment with bisections and trisections, the circle was divided into spaces of 10° ; then by obtaining the arc of 9° by trial in the arc of 180° , the circle can be divided into spaces of 1° , and by similar means into smaller spaces if required.

Ramsden's method of dividing, consists in the use of the beam compasses, as employed by Bird, and the method of the Duc de Chaulnes combined. The circle is first divided by the beam compasses and the position of the dots accurately ascertained by means of microscopes, and corrected accordingly, by pressing the dots with the point backwards or forwards by the hand. This method is capable of a great degree of accuracy, but is tedious in the extreme.

The next great improvement was effected, and is described in the *Phil. Trans.* for 1809, by Mr. E. Troughton, in whose hands the Art has arrived at a high degree of exactness; but there are various difficulties in the application and construction of the apparatus, which it has been the object of the method now to be described to avoid by adopting principles perfectly independent of mechanical action, and governed only by vision, aided by the most powerful optical means. The roller used by Mr. Troughton is wholly rejected, and the apparatus employed is so constructed, that the character of the circle to be divided, whether slightly porous or defective, does not affect the accuracy of the operation. The method of cutting the original divisions is simple and rapid, and in number they scarcely exceed one-third of those employed by Mr. Troughton; thus reducing the labour of observation and computation, while a great practical convenience is gained by making each original division a division of the circle. The construction of the apparatus is firm, and its motion

Machinery.

Manufac-
tures.

Description
of Ros's
apparatus,
Pl. xxiv.
Fig. 3 and 4.

free from elasticity and friction; and when once adjusted, the accuracy of the divisions depends entirely upon the permanence of certain parts, which are so secured as to prevent the possibility of derangement. From the time of cutting the original divisions to the completion of the operation, the circle is free from any attachments of dividing apparatus, and is only viewed through the microscope, so that the ultimate dependence is upon vision.

(325.) The required apparatus consists of the following parts. A small circle, 10 or 12 inches diameter, divided into spaces of $3^{\circ} 45'$, or 96 parts, by the usual dividing engine, or by any ordinary means; two micrometer microscopes represented in pl. xxiv. at *a b*, fig. 3 and 4, which are top and side views; an arc *c c* of the length of $3^{\circ} 45'$ of the circle to be divided; a cutting frame *d e*; and a frame *f f g g* to support the apparatus. The frame *f g* consists of a bottom and top plate connected by two strong pillars; one of them is represented at *h*, the front one being moved to show the other parts. In the bottom plate are screwed the nuts *i i*, fig. 3, which form adjustable feet for the frame; these nuts are perforated, and the screws *j j* pass through and fasten the whole securely, after being levelled by the nut *i* and level *l*. The upper plate is secured to the pillars *h* by two screws and collets *k m*, moving on *k* as a centre, and adjustable at *m* by the pushing screw *n*, for the purpose of setting the cutting point *o* (which is attached to the upper plate *f*) to cut a radiating division on the circle to be divided; an arc and index at *p*, fig. 4, indicate the inclination given. To the upper plate is likewise attached the hollow centre *g*, fig. 3; in this works a male centre, the flanch of which is seen at *r*, fig. 3; this supports the bar *s s*, which carries the microscope *a b* and level *l*. The microscopes are secured to this bar by two pulling and two pushing screws *t t*, *t t* passing through a flanch *v*, and acting in and on the bar *s*. The microscopes are secured to the flanch by fitting into strong tubes *u u*, fig. 3, which are soldered into the flanches *v v*, and when adjusted to distinct vision, can be fixed in that position by the clamping rings *w w*. The handle *x x* for the cutting frame is attached to the perpendicular slide *d*, having a double joint at the point where it is fixed; in order to prevent any unequal pressure from producing a lateral motion of the cutting point, the other end is connected to the upright dovetail slide 3, 4, which forms part of the apparatus for moving the cutting point, and will be found fully described in the account of the dividing engine. The openings are for the purpose of permitting the arc to be viewed through the microscope during its passage over it, and to pass the centre *q*, when continued to the cutting frame.

The first part of the process is to make ninety-six divisions at a convenient part of the circle, according to the arrangement of the cutting point and microscope *a*, upon silver dots inlaid for that purpose; and it may be here necessary to remark, that the part of the circle upon which the divisions are to be made must be turned with the most scrupulous exactness; and when the greatest degree of accuracy is required, and microscopes of high power are employed, it will be necessary to turn the circle in its ultimate position, and when the whole is of the same temperature. To obtain the divisions, let the instrument be placed upon its stand, or on a temporary one, composed of the same metal as the circle, in its ultimate position, and fix the small circle upon and concentric with the one to be divided. Fix one of the

microscopes over the divisions on the small circle, and fix the cutting point over the part of the circle intended for the original divisions. Having determined the zero point of the circle, place the cutting point and microscope in such positions that the first original division shall be the half of $3^{\circ} 45'$ (by ordinary estimation) from it. The apparatus is then ready, and the whole of the ninety-six divisions may be cut by successively bringing a division on the small circle to bisect the cross in the microscope.

This small circle and microscope may now be removed, and the second part of the process performed; (which is the same as Mr. Troughton's, except that the first step is a trisection instead of a bisection;) but as the process can be carried on by bisection to $11^{\circ} 15'$, it has been performed both ways, the corresponding results being a severe test of the accuracy with which this most important part of the operation is performed. Likewise testing the mechanical action of the instrument, the errors being ascertained by bisection, precisely on Mr. Troughton's plan, we cannot do better than quote his description.

(326.) "The circle remaining in its ultimate position, the two microscopes must be firmly fixed to the stand of the instrument on opposite sides, and the wires brought to be bisected by the first or zero division, and the one which should be 180° distant. Now, the microscopes remaining fixed, turn the circle half round, or until the first microscope coincides with the opposite division; and if the other microscope be exactly at the other division, it is obvious that the divisions are 180° apart, or in the true diameter of the circle; and if they disagree, it is obvious that half the quantity by which they disagree, as measured by the divisions of the micrometer head, is the error of the opposite division; for the quantity measured is that by which the greater portion of the circle exceeds the less. It is convenient to note these errors + or -, as the divisions are found too forward or backward, according to the numbering of the degrees; and for the purpose of distinguishing the + or - errors, the heads are numbered backwards and forwards. One of the microscopes remaining as before, remove the other to a position at right angles, and considering for the present both the former divisions to be in their true places, examine the others by them, *i. e.* as before, try by the micrometer how many divisions of the head the greater half of the semicircle exceeds the less, and note half the quantity + or - as before; and do the same for the other semicircle. One of the microscopes must now be set at an angle of 45° with the other, and the half difference of the two parts of each of the four quadrants registered with their respective signs. The microscopes must now be placed at the distance of $22^{\circ} 30'$, and the half differences of the parts of all the arcs of 45° measured and noted as before, thus descending by bisections to $11^{\circ} 15'$. During the whole of the time that the examination is made, all the divisions, excepting the one under examination, are for the present supposed to be in their true places; and the only thing in this important part of the business, from first to last, is to ascertain, in divisions of the micrometer head, how much one of the parts of the interval under examination exceeds the other, and carefully to tabulate the half of their difference.

"The foregoing examination furnishes materials for the construction of the Table of half differences or apparent errors. The first line of this Table, with a distance of 180° , is the real error of 180° . The second

Method of
testing the
divisions, as
practised by
Troughton

Manufactures.

Pl. xxv.
xxvi.

From a series of observations made upon several instruments, to determine the errors of the ordinary dividing engine, it occurred that in large arcs the errors varied from 5" to 17", but on the examination of some smaller arcs, the mean error was about 4"; and as the linear value of this angular error will be directly proportional to the radius, it follows that if an arc, as in plate xxv. fig. 12, is divided into angles at a short radius r , so that when placed at a longer radius R , a point moving round the centre c , and passing over the divisions on that arc placed at R , makes equal angles $a a$ when in coincidence with each division, the angular error in the

equality of those spaces will only amount to $\frac{r}{R} e$, e being

the angular error of the part of the dividing engine used in cutting the divisions at the short radius; and if this operation is successfully repeated by attaching the arc to the engine plate, and fixing a microscope over the divisions instead of using the screw, as in the first instance, the utmost limit of accuracy that the motions of the cutting frame and vision, assisted by the most powerful means, is capable of, can be obtained. In applying this principle to obtain the divisions on the arc, let A , plate xxvi. fig. 11, be the centre of the circle to be divided, $A M$ the shorter radius of the original divisions, M the micrometer from which the apparent errors were registered. This microscope is attached to an arm $b m$, and moves on a centre c , (the same as marked $s s$ and q in fig. 1, pl. xxiv.) and m is the other microscope observing the arc.

Let $M b$ be the half of an original space, then c will be the angle when the microscope M is observing the original divisions in its extreme position, and its opposite angle being equal, it will also be the extreme angle on the arc, to obtain which there is the triangle $A b c$ with the angle A given, being the half of an original space $= 1^\circ 52' 30''$, and $b c$ may be ascertained according to convenience, or the determined ratio of the radii, and $A c = b c + A M$; then $b c : \sin A :: A c : \sin b$,

$$\therefore \sin b = \frac{\sin A \cdot A c}{b c} \text{ and } c = 180^\circ - (A + b). \text{ And}$$

this is the form for computing all the angles on the arc; for as the instrument is divided into spaces of 5', the angle at A is successively the preceding angle $- 5'$, and the sides $A c$ and $b c$ are constant.

It will now be seen, that the length of the original divisions must be equal to the versed sine of the angle c to the radius $b c$, or $c M$, and that they should be truly radiating. It will also be observed, that as the error of the division is taken at its shorter radius, it will be greater as the radius is increased, and likewise that, at the time of observing, the micrometer was a tangent to the circle; but when the microscope is observing the extreme division on the arc, and the original division is brought in the field of the other microscope, it is observing a different part to that used in obtaining the error, and the micrometer is not a tangent to the circle. These circumstances show the necessity of cutting the original divisions in their true places before dividing the whole circle; for, if the erroneous divisions were used, as in Mr. Troughton's plan, it would be necessary to apply a correction at several stages of the original space, according to the extent of the real error and the angle c , which would be rather a complex operation and introduce the liability of mistake.

The next step, therefore, is to cut the original divisions

in their true places, which is performed by using the cutting frame the same as in cutting them originally and adjusting the point to cut a radiating line by making long, opposite divisions on thin temporary pieces of brass, and to observe the error at each end of one of them, and incline the point by the screw n , fig. 4, until the errors are alike, or until there is no error, when one of the microscopes is moved to each end of the division. Then fix the cutting frame at the right convenient distance, and also fix the micrometer, which was used in obtaining the apparent errors, to the upper plate of the frame of the apparatus by a temporary arm, and previously to cutting each division, place the micrometer head at the real error of the division under the microscope, $+$ or $-$, as extracted from the computations. This operation being completed, it gives additional satisfaction to examine the divisions again, and if correct, the whole divisions may be cut on the circle.

The apparatus complete, as represented at fig. 1 and 2, is used in this operation, and is to be placed on the stand in such a position, that the distance between the centres $A c$ shall be as nearly equal to that used in the computations as ordinary means will command. The cross is now to be taken out of the microscope a , and a thin plate of metal put in its place, with a small hole perforated, such that the image of the divisions will occupy about three-quarters of its diameter; then to bring the various parts into adjustment, first make the surface of the circle perfectly level, and the centre of the apparatus perpendicular by the level l attached to the bar s ; this will preserve the distinctness during the passage of the microscope a over the circle, while the microscope b is passing over the arc. The next adjustment is to make the centre of the circle the centre q , and the middle of the arc c in a line, and that the microscope b , in moving between the extreme divisions of the arc, shall move the microscope a accurately over an original space. To effect this, it is necessary to have a boundary line described to the original divisions, which should be made at the time the circle is turned, with a fixed point, so that it may be perfectly concentric, and the original division should be made to intersect this circle. Half way between any of the original divisions, there should be a division, which is to be made at the time of cutting the original divisions, and the error of it obtained at the time the original divisions were verified; then, having placed the microscope b over the divisions on the arc, (which should have its middle division cut at the time of cutting the other divisions,) bring the hole in the microscope a over an original division at the intersection of the circular line. The circle remaining stationary, move the microscope to the next original division, and observe if the intersection of the circle and original divisions are in the hole in the microscope; if not, move the circle of the microscope, and repeat the operation until the intersections pass the centre of the hole in the microscope in its course over the circle. The circle remaining in this position, place the microscope a over the division between the original divisions, allowing for its error; then adjust the microscope b for its cross, to be bisected by the middle division on the arc. The microscope b is now to be placed at an extreme division on the arc, and an original division brought into the other microscope; then move the bar s until the other extreme division of the arc bisects the cross, and observe if the original division bisects the hole in the other microscope; if not, the

Manufactures.

microscope *a* must be moved to or from the centre of the circle, as the microscope is found to measure too small or too great a space; for, the original divisions being radiating, the nearer the microscope is moved to the centre of the circle, the smaller will be the linear value of an original space, and *vice versa*. These adjustments must be carefully performed, and verified at intervals, until the angle moved through by the bar *s*, governed by the arc *c*, coincides accurately in the microscope *a* with an original space, and the middle divisions of the arc and original divisions agree with the cross and hole in the microscopes at the same time.

Process of cutting the divisions.

(328.) The apparatus is now ready to cut divisions: to perform which bring the micrometer head of the microscope *a* to zero; and let the cross in the microscope *b* be bisected by an extreme division on the arc *c*; then bring the zero original division to bisect the hole in *a*. It will be recollected, that the zero original division was placed half an original space from the real zero; and when the apparatus is placed as above directed, the cutting point will be found half an original space from the original division, so that the zero division of the circle will be in its right position. The microscopes and circle being in this position, let a division be cut, then move the bar *s* by the pushing screw *y*, until the next division on the arc bisects the cross; then move the circle by its tangent screw until the original division bisects the hole, and cut again. Proceed in this manner through the whole original space; then leaving the circle in the position in which the last division was cut, move the bar back to the first division on the arc again, and observe that the next original division now bisects the hole in *a*; then proceed as before to cut the whole of the divisions in that space, and the same for the whole of the circle. It may be observed, that a test of the permanence of the adjustments of the apparatus is formed at every space by the original divisions bisecting the hole in *a*, when the microscope *b* is moved back to the beginning of the arc.

The long handle *x*, fig. 3 and 4, which moves the cutting point, prevents any partial expansion in the apparatus; and for this purpose the whole may be enclosed and viewed through a plate of glass at the top. A narrow slit will be sufficient for the handle to pass through; the handle *x* serving the same purpose as the connecting bar 25 in the engine, plate xxvi. fig. 1, and is joined like that to the vertical slide 34 of the moving apparatus. But there is an arm 2 attached to *x* which projects under the frame *e* to lift the cutter off the work, when the bar *x* lowers; therefore the action of the lever 22, plate xxv. fig. 1, will be reversed when the point is cutting the divisions, by which arrangement the bar *x* will be raised while making the cut, and lowered to return.

The best light is considered to be an Argand lamp, placed outside the apartment in which the operation is performed, and refracted or reflected through a hole to the divisions. This will likewise give sufficient light in the room to move the adjusting screws and cut the divisions. These arrangements prevent the possibility of partial expansion from the heat of the light, and enclosing the apparatus, prevents the same from the proximity of the body, the breath, or the heat of the hand; and as this is the only thing that can affect the accuracy of the operation in this method of dividing, it must be guarded against in every direction, which the construction of the apparatus greatly facilitates. It

may here be noticed, that the effect of partial expansion must be observed in the second part of the process, when the apparent error of the large arcs is taken. For this purpose there should be several thermometers applied at various parts of the circle; and before observing, it should be ascertained that they all indicate the same temperature. This is of the greatest importance, as the errors obtained by trisection, if this is not scrupulously attended to, will not agree with those obtained by bisection; but in the smaller arcs it is only necessary that they individually should be at the same temperature. The microscopes used have the focus of the object glass about ten times the distance of the plane of the divisions from it, and the screw has 100 threads in an inch; this is moved by a micrometer head having 100 divisions, so that by this arrangement the value of each division is $\frac{1}{10000}$ of an inch. The cross wires are placed at the angle 20° , and, with a little experience and fine optical powers, the bisection of the cross by a division may be observed within this value.

The method of filling up an original space by copying an accurately divided arc by microscopic means, may be applied in various ways. First by a frame rolling on the arc of the circle carrying the microscopes, and the cutting frame and arc to be copied on the stand. The microscopes may also be attached to a bar having a Y at one end bearing on a cylinder on the centre of the circle; but these modes are objectionable, as they encumber the circle to be divided.

(329.) This method of dividing can with facility be applied to linear instruments. For this purpose a plane of brass, or cast iron, about eight inches wide, and of the requisite length, having its edges perfectly straight, is necessary to support the apparatus, which in this case is to move along the bearer or plane, being guided in its motion by studs rubbing against the edge and kept in contact by a spring and rollers acting on the other edge. The series forming the original divisions (supposing a scale of inches

Linear dividing.

and parts) is $\frac{36}{3} = 12$ in. $\frac{12}{2} = 6$ in. $\frac{6}{2} = 3$ in., the errors

of which are to be taken and computed as directed for circular dividing; and these can be verified by bisection

down to 4.5: for $\frac{36}{2} = 18$ in. $\frac{18}{2} = 9$ in. $\frac{9}{2} = 4.5$ in. The

space of 1.5 being filled up with equal and parallel divisions, the angles on the arc can be obtained by making the difference of the tangents to the radius *c M*, plate xxv. fig. 11, equal; for suppose the scale to be divided into tenths of an inch, then the first tangent from the middle of

the arc $= \frac{1.5}{2}$ in. $= .75$ in. and the tabulated natural

tangent of the extreme division on the arc will $= \frac{.75}{c M}$,

and the tabulated natural tangent of the other angles will be successively the preceding linear value on the

scale $\frac{.1}{c M}$. The original divisions are to be cut in their

true places, precisely as described in circular dividing; and in cutting the whole of the divisions, the only difference is, that the apparatus is movable instead of the instrument to be divided.

By this system accurately divided scales of any description can be obtained; as it appears peculiarly

Manufac-
tures.

adapted for those of zenith sectors, the application of which must be sufficiently obvious.

Description of the Dividing Engine.

Description
of the en-
gine at
large.

(330.) Since the construction of the endless screw-dividing engine by Ramsden, there has been but one improvement made of any consequence, viz. that of Mr. Allan, which appears well calculated to correct errors arising from the gradual increase or decrease of the size of the teeth in the circle; but where the asperities are to be removed by such an obtuse cutting angle as that presented by a serrated cylindrical screw, the pressure required is too great to be compatible with those delicate operations which are necessary to obtain the accuracy which such an engine ought to possess. There are other difficulties arising from the heterogeneous nature of even the best steel that can be obtained for forming the screw, likewise the porosity and want of homogeneity in the cast materials forming the circle. These considerations, which were deduced from a practical acquaintance with the subject, led Mr. Ross to a mechanical modification of the previously described primitive method of dividing, of which the engine now to be described is the result.

The principal mechanical action, or that which regulates the motion of the circular plate, is the reverse of the endless screw, which acts by driving. In this engine a rotary motion is applied by an independent apparatus, and the circle is stopped at its precise angular position by the contact of plane and spherical surfaces of hardened steel, their truth being ascertained, by preliminary experiments, to be far within the limit of admissible error.

The engine is represented at fig. 1, plate xxv. and xxvi. The former is a top view of the engine, and the latter a sectional view, 1 1 is a frame of cast iron, on which the engine is mounted; 2 2 the hollow centre screwed to the frame by the flanch 3 3; the axis consists of two similar cones 2 2, which are screwed to the circular plate *a a a a* by its flanch. Around the circle are screwed 48 cocks, *b b*, &c., having capstan-headed screws *c c* (shown half the real size in fig. 2 and 3, plate xxv.) passing through them parallel to the plane of and tangent to the circle. The ends of the screws are hardened and ground flat and square to the axis; this is effected by screwing them into a piece of brass about one inch and a half in diameter, whose thickness is rather less than the length of the screw. This must previously have its surface turned flat upon a true screw arbor, then the projecting end of the screw is to be ground off upon a flat metal surface until it is level with the turned surface of the brass. These screws may be fixed in any position by the tightening screws *d*. The weight 4 on the lever 5 supports so much of the weight of the circle as to let it move pleasantly. At one end of the stand of the engine is a sliding plate which carries the worm *e e*; it is movable by the screw 7, for placing the worm in or out of gear with the cocks on the circle. The plate is brought into its precise position by three steady pins 9 9, and secured by four binding screws 10 10; two of them, with one steady pin, go in underneath, and are not shown. The distance between the shoulders of the screw 7 being greater than the thickness of the standard 8, is for the purpose of preventing strain upon the steady pins. The worm *e e*, or one single revolution of a square-threaded screw moving on a horizontal axis, having the distance between its threads equal to the distance of the ends of the tangent

screws *c c*, &c. on the circle, is pierced parallel to its axis with ninety holes to receive capstan-headed screws *f*, fig. 2, plate xxv. with spherical ends; these have also tightening screws *g*. The pivots of the axis are turned with a screw tool so as to have rings on them, and the bearings have corresponding rings within; this prevents any shaking; one of the pivots is seen in fig. 6. On the outer rim of the circle a groove *h*, fig. 3, is turned, in which a slight catgut *i i*, fig. 1, passes round, moving over pulleys *j j*, and then under the weighed pulleys *k* and *l* at each side; the weight *k* being superior, always brings the screws on the circle in contact with those in the worm *e*. The gut *i* rises from the weight *k* to the clamp *m*, where it is bound fast; it then passes above the engine on a notch *n*, and then down to the pulley *b* in an endless band, of such a length that when one weight is up the other is down. When the weight *k* is down, the clamp *m* is to be loosened and *k* rises, this lets the weight *b* run down the clamp; *m* is then to be tightened, and the whole is ready for action again. The portion which passes over the engine is broken away, that it may not interfere with the view.

The four pillars 11 11 support the triangular bar 12 12, on which slides a saddle 13, to which is appended the cutting apparatus, of which fig. 6 is a front view, and fig. 7 is a side view; 14 14 is a sliding plate to adjust the height of the swing frame 15 16; the part 17, in which the cutting point is fixed, may be secured at any inclination by the screws 18 18. The pedestal 19 supports the moving apparatus; fig. 8 shows it partly in section, and fig. 7 is a front view; 20 20 is a dovetail sliding bar, with a standard 21 rising from the middle; 22 is a forked lever, the prongs of which embrace the standard to give an alternate motion to it and the bar 20; the diameter of the standard is about two-thirds of the opening in the forked lever. Fig. 8 shows the frame in which the bar 20 slides with a stud 23, on which the lever 22 moves. To the sliding bar 20, plate xxvi., is joined a vertical sliding frame 24, to the sliding bar of which is joined the adjusting bar 25, which connects this moving apparatus to the swing frame 15; the vertical sliding frame 24 is also joined to the sliding bar 20, and connected to the standard 21 by an adjusting bar 26, in order to give that inclination to the sliding frame 24 which prevents motion in the swing frame and cutting point during the rise or fall of the connecting bar 25. To the swing frame 15 is screwed a double joint 27, shown fig. 7; in this one end of the connecting bar 25 moves concentric with the axis of the cutting frame 16, but quite free from it. Upon the bar 25 is mounted a frame 28, fig. 1, 7, and 9, in which a bar moves by the adjusting screw 29; at the bottom of this bar is a square opened cross, to which another small bar 30 is screwed, and from the frame 16 projects a cylinder 31, fig. 6, which passes through the opening and rests upon the bar 30, so that when the bar 25 rises it lifts the cutter 32; fig. 9 is a balance weight. A lever 33 is joined on the sliding bar 20, shown in fig. 8 and 10; the long arm passes under the upright sliding bar 34 in the frame 24, and the short arm terminates in an inclined plane, which rises in the space between the fork and the standard 21; then during the motion of the fork through the space which is not occupied by the diameter of the standard, it presses the short end of the lever down, and by the alternate motion permits it to rise before the inner sides of the fork act upon the standard 21.

Machinery.

Manufactures.

Now, to exemplify the method of using this apparatus, let the handle 22 be in the dotted position nearest the engine, plate xxv., then the short end of the lever 33 will be depressed and the slide 34 elevated, and with it the bar 25 and frame 28, and let the cutting point be lifted off the work to be divided; then move the handle 22 gently from the engine; this will permit the short end of the lever to rise between the fork and the standard, and the long end will be depressed, and with it the slide 34, the connecting bar 25, and the frame 28, until it has left the cutting point resting on the work; the inside of the fork will now be nearly in contact with the standard; move the handle further, and this will press forward the slide 20, the connecting bar 25, and the swing frame 15, which will draw the swing 16 and cutting point along with it, and make a division; then reverse the motion of the handle, and the fork will press the short end of the lever down; this will raise the slide 34, and with it the cutting point, from the work; the other inside of the fork will now be nearly in contact with the standard; move the handle further, and the slide 20, with the connecting bars and cutting point, will be brought back ready to cut another division. The lengths of the divisions are regulated by a cross piece 36, fig. 8 and 10, on the top of the standard 21, coming in contact with the end of the screw 35, and the edge of the circular steel plate 37. The short divisions are limited between the ends of the screw 35, and the edge of the steel plate, and the longer divisions are given by notches in the steel plate, which let the stop 36 move so much further; and these notches are presented in the proper order by a ratchet wheel 38 (which moves on the same centre pin as the steel plate shown in fig. 8) and a click 40, which is connected to the forked lever 22 by an adjustable arm and stage 39, supported by three pillars shown separately in fig. 8; this click is kept in contact with the teeth of the ratchet wheel by a slight spring, so that the same motion which operates in cutting the divisions constantly regulates the lengths of them. When cutting from the centre, the lever represented, fig. 12, is to be used instead of that previously described; and when the long and short divisions are on the outer circumferences, the steel plate 37 and screw 35 change places. By this method of cutting the divisions the body may be at some distance from the cutting point and circle, which prevents the effects of partial expansion in the dividing apparatus and instrument to be divided, which must necessarily occur in the course of an operation in the ordinary method, from respiration and the heat of the hand. It also cuts the divisions uniformly straight and equable, likewise obviates the necessity of circumscribing the divisions with a deep coarse line, thereby considerably reducing the liability of breaking the point, which is of great importance in the use of the diamond.

The lever, to which is attached the handle *w*, regulates the motion of the worm and circle; this lever passes through the pedestal, and moves upon a centre pin within it; to the short end of the lever *z* is joined the connecting bar *x x*; near *z* is an adjusting screw, by which the motion of the lever and bar is limited; the other end of the bar *x x* has a double joint, by which it is connected to the arm *y*, fig. 5 and 6; the opposite arm 44 carries a spring click: these arms move in a hollow axis concentric with the worm, but independent of it; a section of this is shown in fig. 6. The axis of the arms *y*, 44 is supported by the standard

47, which is screwed to the plate 66, which carries the Machinery worm, the spring click moves the ratchet wheel 45 attached to the worm, and is stopped at this end of the bar by the arm *y* abutting against the stud 46, fig. 5, and is limited in its motion the other way by its screw at *z* stopping the motion of the lever. A spring 41, faced with leather, presses against the catgut *i* and rim of the circle; this prevents the motion of the circle, until the spring is removed out of contact by the pressure of the screw 42. Now let the handle *w* be in the position represented in plate xxv., then move the handle from the engine; this will move the bar *x x* the contrary way, and will move the arm *y* from the centre until it stops against the stud 46; this motion will have brought the arm 44 and spring click towards the centre, and have moved the ratchet wheel and worm round, and, consequently, moved the screw in the worm out of contact with the screw in the circle; the handle *w* is now to be moved back, when the click passes over the teeth in the ratchet wheel, and the worm remains stationary; the screw 42 will then come in contact with the spring 41; now press the handle a little further, (as represented by the dotted lines,) and this will remove the spring out of contact; the weight *k* will immediately give motion to the circle, and bring it in contact with the worm. In removing the spring out of contact, the power should be gently applied, so that the circle slides round and does not drop with any violence against the screw in the worm; and when the contact of the screws is complete, the spring should be kept out of contact with the circle, then at the distance of cutting the division the circle is under no influence but the constant force of the weight *k*. The length of the screw at *z*, with several holes in the bar *x* to join the bar to the lever, afford convenience to escape over as many teeth of the ratchet wheel 45 as may be required.

In fig. 1 is an iron segment 48, supported on three arms projecting from the iron stand 11; upon this are fixed three pillars, 49, 50, 51; two of them hold micrometer microscopes, 52, 53, the other, 51, holds the screw 54, which acts against the piece, fig. 9, when it is screwed on the circle, and the worm *e e* is drawn out of gear. This is used when dividing vernier scales, these being obtained from divisions made by the engine upon the silver ring by means of the micrometer microscope.

This description has chiefly applied to the construction of the engine for transferring divisions by the mechanical action of contact; it now remains to be described how the various parts are regulated, according to the principles laid down in the primitive method of dividing.

Corresponding to each cock *b*, on the circle is inlaid a small circular disc of silver to receive original divisions. These are to be made, and the errors of them obtained, as directed in the primitive method of dividing; then the ends of the screws *c* on the circle may be adjusted to their true position, by fixing the microscope placed at zero over the original division zero; when a screw *c* on the circle is in contact with one in the worm *e*, then move the worm one revolution, and the next screw in the circle will be in contact with the same screw in the worm, and the next original division will be under the microscope; place the micrometer head at its real error, and move the screw *e* on the circle until the divisions bisect the cross in the microscope, and repeat the same operation with the whole 48 screws. The means for adjusting the screws *f* in the worm are

Manufao-
tures.

similar to those in the primitive dividing for filling up the original space; but in this case the constant sides of the triangle are different.

Let c , fig. 4, plate xxv. be the centre of the dividing engine, cb its radius, and $ba = \frac{bc}{m}$; then, as before, bd

= half an original space, and as the angles are to be $5'$, (this being the angle given by the number of screws, and affording all the variety in dividing astronomical and mathematical instruments,) the angles at c will be successively $3^\circ 45' - 5'$, $(3^\circ 45' - 5') - 5'$, &c.; then

$$(ac + bc) : (bc - ac) :: \cot \frac{c}{2} : \tan \frac{a-b}{2} = \frac{bc - ac}{ac + bc} \cot \frac{c}{2};$$

then

$$\frac{a-b}{2} + \frac{a+b}{2} = a, \text{ and } 180 - \left(\frac{a-b}{2} + \frac{a+b}{2} \right)$$

= the external angle at a . Then, for the most convenient form of computing the angles, this reduces to

$$\frac{bc - ac}{ac + bc} \cot \frac{c}{2} = \tan \frac{a-b}{2}, \text{ and } 90^\circ + \frac{c}{2} \frac{a-b}{2}$$

= the angle to be cut upon the arc, fig. 10.

It is necessary that the boundary lines on the scale should be described while revolving with the engine, and that the first and last division should intersect these lines; the dividing point should also be adjusted to cut a radiant line. This affords the method of making the two centres and the middle of the arc in a line when placed at its longer radius. For this purpose it is only necessary to make the intersection pass the centre of the hole in the microscope. The other microscope is now fixed over the original divisions, and the one over the arc must be adjusted until the space between the extreme divisions on the arc equals an original space, as directed in the primitive dividing. The screws f in the worm e are now to be adjusted until each division on the arc bisects the hole in the microscope when the screw in the worm is in contact with the one on the circle. The engine should now be worked round several times, and the adjustments repeated at intervals, until they are found to be constant and perfect. Thus, by the most delicate operations, the engine is rendered capable of moving through its angular spaces with a great degree of accuracy and certainty; for without very minute examination and adjustment the engine can be regulated within $2''$; and from observations made with delicate adjustment and minute observation, the contacts may be made to a division of the micrometer head which is one-fourth of a second.

There are two sources of error in this Machine: first, the difference of expansion in the worm and stand, the worm being of bell metal, and the stand of cast iron, then the worm expanding above $\frac{1}{100000}$ parts of its whole length for each degree of temperature, which is about one-fourth of a second, and the expansion of cast iron being about two-thirds that of bell-metal, the difference

$$\frac{1}{4} - \left(\frac{2}{3} \text{ of } \frac{1''}{4} = \frac{1''}{12} \right);$$

so that it is necessary to adjust the worm in a mean temperature, then this source of error will not affect the accuracy of the engine in any material degree when the temperature is between 35° and 70° of Fahrenheit. The

other source of error is, that the ends of the screws on the circle are not perfectly square on their axes; and as the spherical ends of the screws in the worm do not come in contact with the flat ends of those of the circle at the same point in every contact, but differ nearly as the secant of the angle, (this at the extremes is about one-thirtieth of an inch,) therefore any difference in the inclination of the ends of the screws on the circle will produce error. This error can be halved by adjusting the screws on the circle against that screw in the worm which comes in contact in the mean point; this occurs at the eleventh screw for the extreme; then by removing the microscope so that an extreme screw comes in contact with the screw on the circle, when the original division is under the microscope, the amount of this error can be obtained. In this case, in some places, it amounts to $1''$; so that if all the greatest errors occur at the same time, and all the same way, the error will be about $3''$.

The usual method of centring the instruments to be divided on the engine is very defective, for it often happens that the axis of the motion of the instrument is not truly in the centre of their permanent fittings; and this, with other causes, produces a disagreeable eccentric error in circular instruments, though really of no consequence where there are two verniers, for the angle observed is an angle within a circle, and is measured by half the sum of the intercepted arcs, therefore half the sum of the opposite reading will be the true angle; but in instruments having but one vernier, and more particularly in sextants, this produces serious error, for the eccentric error has been seen such that it might produce an error in a sextant to the extent of $3'$. This led the inventor to devise a method of centring, whereby the axis of motion of the centres of the instrument may be made in a line with the axis of motion of the centres of the dividing engine, and is thus effected. Suppose the instrument to be a sextant, then to the flanch, fig. 2 and 5, plate xxvi. of the male centre is screwed or cemented a double dovetail slide qr , fig. 2, 3, and 4, the slides at right angles, with drawing screws ss and spiral springs tt to each slide, and on the upper slide is made a dot. The instrument is laid upon the centre of the engine plate, and over the dot is fixed a microscope, fig. 11, with cross wires. The male centre o is then made to revolve, and the slides adjusted until the dot is perfectly stationary; the engine plate a is then made to revolve, and the instrument is moved by the pushing screws uu and opposite spring slides vv , fig. 5, the dot is again stationary during a revolution. Thus by the first adjustment, the dot is in the axis of motion of the centre of the instrument, and by the second the same is made in the axis of motion of the dividing engine. For other instruments there are four adjustable dots placed at a convenient distance from the centre, and these are made to pass a wire in the microscope while revolving on its own centre likewise, when on the engine. This affords a great convenience in circular instruments, and is an improvement of considerable importance in sextants.

(331.) *Engine for drilling.*—The common process of drilling with what is called the drill bow is sufficiently well understood, but for the heavier sort of iron work more powerful means must be had recourse to. These means may be supplied by cranks worked by men, or by wheels and shafts driven by water or steam. In plate xxiii. fig. 11, is represented an elevation of a powerful hand engine for this purpose. Here AB is the ground-floor, A, B , Drilling engine.

Manufac-
tures.

and C being large blocks of stone laid down to receive and support the cast iron frames; to secure these to the stones, iron pins with screws cut on them are first let into the stones and passed through holes cast in the several plates, to which they are then firmly screwed down by nuts. D E are two standards for carrying the winch or handle F, intended to be worked by three men. G is a strong double cast iron frame, intended to support the bevelled wheel which works the horizontal bevelled wheel I; through the centre of this wheel slides the drill shaft, so that it may descend freely through it, and follow its work as the drilling proceeds; in some cases this shaft is square, but it is more commonly cylindrical, with a recess to take a feather left in a cavity of the wheel's centre. In the collar L the drill shaft also passes freely, and the latter is united above with a rack, as seen in the drawing. This rack is worked by a small pinion m, by means of a wheel fixed on the same axle with it, but being on the other side of the frame, is not seen in the elevation; over this wheel passes an endless chain, which hangs down, so that a man pulling on it may raise the rack and drill shaft to any required height, at which it will be supported by means of the ratchet wheel and a spring pall, seen on this side of the frame at M.

N N is an iron stage, which may be raised to any required height and secured there by means of holes left in two standards O O, one only of which can be seen in the figure, the other being between the two sides of the principal frame, but its situation is shown by the dotted lines. P is a pit sunk in the floor of the building for the convenience of turning downwards any long arm or other part of the ironwork which may be required to be drilled by the engine, such as the iron knees of ships, and various other heavy ironwork; when, however, it is not required for use, it is covered over by flooring boards, and the engine then assumes a very simple and compact form. W is a fly wheel to give a steadiness to the motion, and is what the workmen call loaded with wood on the circumference towards where the handle is placed; that is, square holes are left in its rim, which are filled with wood; this is intended to remove a weight towards that part equal to the crank, so that the latter may be balanced by the other side of the wheel, and thereby stand in any position in which it is placed, instead of always descending to its lowest position, as it would do without this or some similar contrivance. The drill H is inserted in a socket in the bottom of the shaft, and is there secured by a bolt, and may of course be shifted and changed according to the size which the work immediately in hand may require. When the hole is very large, as for instance two or three inches, a hole of a less size is first drilled, and then a tool is used instead of a drill to enlarge it, fitted with a cutter on each side, and this cutter is changed as the work proceeds till the proper dimension is attained.

The drilling engine here described is one at present being erected in his Majesty's Dock-yard at Woolwich, constructed by Mr. Kingston, an ingenious millwright of Portsmouth. In the same establishment are two other more powerful engines for drilling which are worked by a shaft turned by the steam engine, which are in their principle of action nearly the same as the preceding, except that the principal shaft driven by the steam engine is much higher, so that the drill receives its motion entirely from above; and the rack by which it is elevated is also considerably higher, and works between the two parallel sides of a cast iron frame, but

the drill is elevated, and the pressure brought upon it when at work by an endless chain, as already described.

(332.) *Engine for cutting files.*—This is rather a desideratum in Mechanics than one in actual existence, at least in that degree of perfection which the process requires, although many very ingenious men have devoted a good deal of time and attention to the subject; amongst others, the late Mr. William Nicholson, editor of the *Scientific Journal*, so well known under his name. Another engine also for this purpose is described in the *American Philosophical Transactions*, as also in Gregory's *Treatise on Mechanics*, and in other English Works. Generally, however, it is considered that the best files are those cut by hand; and it will, therefore, be more satisfactory to the reader to be informed of the nature of the manual process, than for us to enter upon the description of a Machine which, however ingenious in itself, is not generally applicable to the purpose for which it is designed. A file which is of the same breadth and thickness throughout, may certainly be cut by either of the engines above referred to, the same degree of percussion being required for every tooth; but if the file be conical, it is obvious that a very complicated engine would be requisite, and great delicacy of operation to cut all round with the precision it may be effected by hand. A chisel also employed in this process is very liable to chip or to get otherwise out of order, which the workman immediately feels, and makes the requisite repairs; whereas with the engine such an occurrence would not be detected till the file was examined. In cutting by hand, the workman sits on a block of such a height as is found convenient, placing himself astride as on horseback; he is also, as in that case, furnished with a leathern strap, answering as stirrups, which strap, passing over each end of the file, retains it in its place by the pressure of his feet; he then, with the chisel in one hand and the hammer in the other, raises the teeth with a dexterity obtained by practice which is very astonishing. In cutting the first side of the file, it is rested on an iron anvil, but when the second side is cut, a piece of thin lead is laid on between the anvil face and file, in order not to damage the side already cut. Great care is necessary in preparing the edge of the chisel, which is in the first place hardened and tempered at a yellowish-brown heat; the edge is next ground very true, and afterwards finished on a turkois stone with oil; it is not made very sharp or fine, the bottom of the cut or tooth requiring to be rather open, to prevent the file from clogging with the substance filed; the edge is, however, required to be very smooth, in order to its slipping easily along the surface during the operation; for it is simply by the feeling that the process is conducted, and if the edge were not very smooth, it would be impossible to preserve that uniformity in the distance of the teeth which is observable in a well-cut file. This sliding is also assisted by a little grease. All these motions are performed with astonishing rapidity: first the chisel, then the hammer, to the amount of between two and three hundred strokes, making as many teeth in a minute; in the larger files, however, which require heavier blows and deeper teeth, the number cut per minute is of course not so great.

Files receive particular denominations; first according to the rate of their teeth, and secondly according to their shape. Files of the very coarsest sort are called *rubbers*, and the next in order to these are called *rough* files, the next are called *bastard* cut, the next *second*

Machinery.
File cutting.

Manufac-
tures.

cut, the fifth *smooth*, and the finest of all *dead smooth*; when distinguished by their shape, we have, *flat*, *half-round*, *three-square*, *four-square*, and *round* files. The first are sometimes of uniform breadth and thickness throughout, they are also frequently tapering, the cross section being a parallelogram. The half-round is generally tapering, one side being flat and the other rounded, the cross section being a segment of a circle. The three-square is, in fact, an equilateral triangle in sections; these are mostly but not always tapering. The four-square file has, as its name imports, a square section. These are generally thickest in the middle, as is the case with the smith's rubber. In round files the section is a circle and the file is tapered.

The flat and square files are made entirely by the hammer. One man holds the hot bar and strikes with a small hammer, another stands before the anvil and strikes with a two-handed hammer, the latter having generally a very broad face for the larger files. These men, from continued practice, strike with such truth as to make the surface smooth and flat, without what is called hand hammering. The half-round and three-sided files are made in bosses; in the former the round part, and in the latter two sides, are formed by the boss, and the flat part by the hammer. The round files are formed by swages similar to those used by a common smith, but having a proper taper. The whole of the working part of the file is finished with the hammer before it is cut off from the rod, and the finished part is then held in tongs and heated a second time to form the fang of the file.

The first process files undergo after leaving the hammer is to soften them by annealing, for they are too hard in their former state, and too rough for the operation of cutting. The annealing is performed in troughs of fire-stone or fire-brick, similar to the cavities in which steel is converted, having the flame of the surface playing on every side and over the top. The trough is filled with alternate strata of the files and coal ashes, or the dust of the coaks formed in the forged hearth. The upper layer of files is covered by a thick stratum of dust, and lastly with a mixture of clay and sand, and the heat should be kept up no longer than till the mass becomes red hot quite through, and the whole is then left gradually to cool.

The next process is the preparation of the surface for the teeth of the files; this is effected differently in different places: in Lancashire it is done by filing, called there *stripping*; but in Sheffield the surface has no other preparation than grinding, which is done by Machinery and at a trifling expense, but by no means so well as by the Lancashire practice of stripping. We have already said what is necessary respecting the mode of cutting, and that between two hundred and three hundred blows and as many teeth are cut per minute. The smaller files are generally cut by women and children, who very soon acquire a great dexterity in the Art.

When the files are cut, the next process is to harden them. This is effected by heating them to redness and then quenching them in cold water; but some previous steps are taken to prevent the action of the oxygen of the atmosphere upon the file when red hot, and a peculiar method of immersing the file in the water is also observed. In the preparing process, ale grounds and common salt are used, the latter being in such proportion as to be just taken up by the aqueous part of the ale grounds,

that is, about three pounds of salt to a gallon. The Machinery files only require to be thinly smeared with this mixture, which, when dry, adheres firmly to the surface till the salt fuses. In heating the file for hardening, a fireplace or oven is formed into which the blast enters; two iron bearers are placed on the upper part of the cavity to support a number of files at once; these are heating gradually while a workman continues to select the hottest, and in a hotter part of the fire gives them the full degree of heat required for dipping them into the water. In this process, all files are dipped in a perpendicular direction: those, however, which have a round side and a flat one, are moved also in a horizontal direction with the round side foremost, without which precaution, files of this shape would warp towards the round side; this arises from the flat side having been more hammered than the round side, which is formed by the concave boss, and does not acquire the same density as is given by the hammer to the flat side. After being thus hardened, the files are brushed with water and coal dust. The surface becomes of a whitish-grey colour, and as perfectly free from oxydation as before heating. In this state they are ready for use.

(333.) *Engine for cutting screws.*—The more common method of cutting screws of the smaller kind, is by hand with taps and dies, which is too well understood to require minute description. To cut the external, or as it is sometimes called, the male screw, a die resembling a common iron nut is employed; but it is formed generally in two parts, and these are fixed in an iron box or die frame with two long handles; the die frame containing the two halves of the die is supplied with one or two screws, or other means whereby the two halves may be opened or closed at pleasure. These parts are formed of well-tempered steel, and the iron pin on which the screw is to be cut is first turned to a proper size; the dies are then opened, the end of the iron pin introduced, and the dies closed so as to take a pretty hard grip of the pin. The workman then, by means of the two handles above referred to, the pin being set fast in a vice, turns the whole round upon the pin, and thus produces a first impression of the thread already formed in the die. Having run the die thus once or twice from top to bottom of the pin, he sets up the dies a little closer by means of set screws, and by repeating the process gets a more defined thread; this is afterwards made still deeper by bringing the dies closer till the thread is properly formed. When an interior screw is to be cut, a proper sized cylindrical hole is first drilled, and then a steel tap slightly tapered, having a proper screw cut upon it and well tempered, is introduced; the head of this tap is left square, over which fits an iron bar with two handles, and by means of these the workman forces the tap down, first by pressing hard downwards and by gently turning at the same time, and thereby making a first impression of the thread. This now giving a direction to the tool, the effort of bearing down is less required, and ultimately a tap, which is throughout of the same dimensions, is introduced and the thread is completed. It may be well to observe that the tap is not cylindrical, as this would leave no cutting points; the tap, therefore, is formed on a pin first turned cylindrical, and which has afterwards segments filed off in two, three, or more sides; the thread being then cut upon it, and the tap properly hardened and tempered, the edges of these parts furnish so many cutting points for forming the interior thread of the female screw.

Manufac-
tures.

A similar principle to this is sometimes adopted to be worked by a steam engine or other power Machine. In these cases the dies are cut in four parts and placed in a frame, whereby they may be opened or closed at pleasure, the die frame is fixed in a strong cheek on the engine bed, and the bolt on which the thread is to be cut is made to revolve by means of the steam engine or other first mover. This bolt having passed through the dies the first time its whole length, the motion is reversed, the dies slightly closed by the workman in attendance, and the operation is repeated till the thread is properly formed. An apparatus of this kind is in constant use in his Majesty's smithery at Woolwich. In the same establishment is also another very excellent engine for the purpose of cutting the larger sort of screws to a great variety of pitches by means of a permanent screw of any pitch whatever.

Screw cut-
ting engine
in Wool-
wich dock-
yard.
Pl. xxiv.
Fig. 1 and 2.

(334.) This engine is represented in elevation and in plan in fig. 1 and 2, plate xxiv. Here A B, fig. 1, represent one side of a strong heavy cast iron lathe bed, both sides being seen in fig. 2, P, Q two heavy cast iron puppets, and C D an axle turning on a point at C, its end being countersunk in order to receive the point, the other bearing on a slightly conical collar in the puppet Q; the two bevelled wheels W W' fit on a part of the axle, and may either of them be thrown in or out of gear with the other bevelled wheel W'', seen in fig. 2, which receives its rotation from a steam engine shaft; S S are two standards on the side of the bed, in which turns in proper collar the screw s s, fig. 1, and the same on the other side, both being seen in fig. 2; E is a sliding frame, through a nut on each side of which the screws s s pass, so that as the screws revolve, this sliding frame is carried from one end of the bed to the other, and in this is fixed the tool by which the threads of the screw to be formed are cut. The cutter is secured in its place by means of the plates and nuts seen in fig. 2. Originally, another cutter was fixed on the opposite side, one having been intended to cut while the slider passed from the end A towards B, and the other as it returned from B towards A; but this arrangement was not found to answer its intended purpose, so that now only one cutter is employed, and the carriage returns free: the cutter is adjusted to its proper place by the screw and lever c d, seen in fig. 2, and the end of the same in fig. 1. T V is a sliding puppet carrying the back centre; this puppet may be placed in any part of the bed, and there screwed fast while any small adjustment for distance may be made by the screw G seen in fig. 2. The bolt or cylinder on which the screw is to be formed being turned perfectly true to two centres, one at each end, this is applied to the points in the mandrel and back centre, and a proper degree of contact is attained by means of the screw G. The end of the cylinder next to the mandrel D is properly secured; an iron chuck is placed on the mandrel, and by means of the driver well known in common lathes rotation is given to the cylinder; and in this form the apparatus may be used for any purpose in which a powerful lathe is required.

But when it is to be employed as an engine for cutting screws, a wheel *w* is fixed on the mandrel, and two equal wheels on the ends of the screws s s; so that while the cylinder revolves by means of the power communicated to the bevelled wheel by the engine, the wheel *w* gives a rotation to the wheels *w'*, *w''*; thus a horizontal motion is given to the slide rest or sliding frame from one end of the bed to the other, and the cutter being pushed forward by means of the screw a first

impression of a thread is formed in the revolving cylinder. When the frame arrives at the end of the cylinder, it presses on the stud *n*, on the lever *l*, and throws the wheel out of gear; a provision which is necessary for stopping the rotation at the proper place, as, without this, a moment's inattention of the workman would lead to the destruction not only of the cutting tool but of the whole apparatus. The tool being now brought back, the motion is reversed by bringing the other bevel wheel in gear, and the cutting frame returns. This wheel is now thrown out of gear by the frame itself, as at the other end; the tool is readjusted and made to cut deeper, and thus the operation is repeated till the screw is completed.

When the screw to be cut is to have the same pitch as the permanent screw which carries the slide rest, the three wheels *w*, *w'*, *w''* are all equal to each other, so that one revolution of the axle advances the cutter one thread; but by changing these wheels, so that the wheel *w* exceeds or falls short of the other two *w'*, *w''* in any ratio, the threads of the new screw may be made to differ from those of the permanent screw in the same ratio. It is therefore only necessary to have a variety of wheels, so arranged that the sum of their two radii shall be a given quantity, to fit the engine for cutting screws of any required pitch whatever.

When a screw is to be cut with a double thread, one thread is first cut, and then the driver is applied to a hole in the iron chuck, directly opposite to its first position; by this means a semi-rotation is given to the new screw, without producing any motion in the cutting frame, and consequently the cutter is now applied to a point midway between the two former threads, when by the same process as before this intermediate thread may be formed. If a triple thread be required, the driver is applied to a hole in the chuck, which is distant from its original position one-third of a circumference, and then again to another at two-thirds the distance, and in a similar manner any number of threads may be formed.

The apparatus for cutting the nut consists of a revolving cutter, turned on the principal axis while the nut itself is fixed in the slide rest, so that while the cutter revolves in its place, the nut gradually advances upon it, instead of the cutter advancing upon the thread as in cutting the screw.

(335.) *Engine for cutting original screws.*—The engine above described, although admitting of being set to cut a great variety of screws, cannot without a very large assortment of wheels cut a screw to any given pitch; and it is, moreover, after every variety that can by possibility be given, still dependent on a screw already formed; and this is generally the case with all our screw cutting engines. Great pains and ingenuity have accordingly been taken and employed to invent an engine that should be competent to cut an original screw, quite independently of any prior existing screw, and of any required pitch. One of the neatest and most perfect engines of this kind for short screws and taps, is erected in the Royal Arsenal at Woolwich, constructed, and we believe invented, by the late Mr. Adam Reid. Here the mandrel, between which and the back centre the cylinder to be cut is fixed, is turned by means of a winch and wheelwork, and on the mandrel is a toothed wheel which works in the teeth of a rack fixed on a long and broad plate of brass which slides between two vertical sides of a frame, faced very truly, so that while the screw is revolving, this brass plate is ascending between

Machinery

Cutting
original
screws

Manufac-
tures.

its guide rods, its breadth being about three inches, and length five feet. At the back of this plate is fixed on a pivot at its centre another similar plate or bar of the same length, and this may be inclined to the former at any angle from parallelism to any angle within the limits of the engine. This last movable rod projects beyond the back of the former and moves freely over it and the level face of the guides at its upper end; it is furnished with an arch head graduated, so that it may be inclined at any angle, and then by a set screw made fast to prevent any motion between the two rods.

A triangular bar parallel with the axis of the engine carries the slide rest or cutting tool; and this is made to come in contact with the inclined rod above described, so that by this means, as the cylinder to be cut is made to revolve, the bar between the two guides rises, and as this rises it brings up with it the inclined bar, and this pressing on the slide rest, urges it forward with greater or less speed according to the degree of its inclination with the vertical bar. If, for example, the swinging bar be fixed parallel with the original rising vertical bar, the slide rest will experience no pressure during the ascent, and the cutter will therefore remain at rest and will only cut a simple circular groove; but when inclined at any angle, the slide rest will during the whole ascent be urged forward a quantity equal to the opening of the two ends of the rod. But as the amount of this opening is much circumscribed by the limited length of the two bars, it is obvious that only very short screws can be cut, such indeed as can be of no use but for taps and guide screws. So that a perfect engine of this kind for long screws is still a desideratum.

Pl. xxiii.
Fig. 12.
Common
engine for
cutting
teeth of
wheels.

(336.) *Engine for cutting the teeth of wheels.*—A common tool for this purpose is shown in fig. 12, plate xxiii. which is found sufficiently accurate for wheels of a smaller kind, and where great precision is not required. Here A is the plate on which the teeth are to be cut; this is fixed concentric with the large brass plate H I, and the cutting is effected by the circular saw B, turned by the wheel and pinion C D, by means of the handle E, while the frame which holds the saw, moving on hinges and resting on a spring, is depressed by the handle F, the place having been previously adjusted by the screw G. The large plate H I contains a number of concentric circles, variously divided by points, into which the end of the spring I sinks at each step, so as to fix the apparatus in the required position, and thereby to equalize the distance and thickness of the teeth, which require afterwards to be finished off with a file.

Maudslay's
engine.

(337.) *Maudslay's engine for cutting teeth of wheels.*—This is an appendage to the lathe of this ingenious engineer. Here a brass plate, similar to that last described, has seventeen concentric circles upon it, each divided into a different number of equal parts, by small holes exactly of the same size; this forms the face of the mandrel, and a thin steel stop, similar also to that described above, adjustable by a screw, so that it may apply itself successively to the holes in any of the circles, is attached to one of the standards of the engine. The plate which is to form the wheel is fixed by means of a chuck to the mandrel, and turned true to its proper thickness and diameter. The fixed rest is then removed, and the slide rest substituted, in which a square bar is introduced having two projecting arms; and between these is placed a spindle carrying the cutters and a wheel, which latter, by being connected with the principal wheel of the lathe, gives a rapid rotation to the spindle on which the

cutters are fixed, *i. e.* to the amount of 7300 revolutions per minute. These cutters, which supply the place of the circular saw, consist of four chisels, fixed perpendicularly into the spindle or axle. The cutter being brought opposite the wheel, and adjusted to its proper distance, it is drawn back, the axle put in rapid rotation, and the whole frame made to advance by a screw for that purpose. Having cut out one tooth, the cutter is withdrawn, the mandrel turned till the pin takes the proper hole in the circle, when the cutter is again put in rapid rotation, and again advanced to the same point as before, cutting thus a second tooth; and thus the operation proceeds till the wheel is completed.

At that part of the frame of the cutting spindle, where the bar which is fixed to the slide rest connects with the two arms or branches, there is a joint by which the cutting spindle can be set in an inclined position for cutting oblique teeth, like those which are to work with an endless screw.

The great velocity with which the spindle turns, soon generates, by friction and resistance, a degree of heat sufficient to expand it very sensibly; but this ingenious mechanist, foreseeing this circumstance, has judiciously compensated for it in his construction, by making the spindle so short as to play loosely in its sockets at the commencement of the motion; but after a few seconds, the expansion is such as to cause the whole to fit together, and the work of cutting then proceeds with accuracy and safety.

(338.) Mr. Roberts, of the firm Sharp, Roberts, and Roberts's Co., of Manchester, has constructed an admirable engine ^{engine.} for this purpose, which cuts with the greatest accuracy and precision teeth of any dimensions, and on every description of wheel. It is impossible, without a great number of figures, to attempt any minute description of this truly ingenious piece of mechanism. We must, therefore, be content with stating, that it consists of a strong cast iron upright frame, carrying another frame, in which is supported the wheel, the teeth of which are to be cut, cast solid, and accurately turned and centred. This, by means of proper wheelwork and endless screw, is so arranged, that one complete revolution of a lever handle turns the wheel such an aliquot part of a revolution on its axis, as answers to the intended number of teeth, or the proper distance of one tooth from another; and by an ingenious contrivance, this lever handle can neither be stopped short nor passed beyond a complete revolution. The motion produced by this revolution on the wheel to be cut, may be varied at pleasure, by a great variety of wheels and pinions fitting each other, and calculated to bring out a great variety of numbers, as we have described in the screw cutting engine. (Art. 334.) By this means the equi-distances of the teeth are accurately insured. This being arranged, a small wheel, furnished with cutters, is put in rapid rotation by the strap from the steam engine, and advancing at the same time against the plain wheel, the first space is cut away. The workman then gives one complete revolution to the lever handle, which, as before stated, locks itself at the end of the revolution, but in no other part. This turns the wheel the distance of one tooth; the cutter is then again put in rotation and advanced, which cuts the second space, and thus forms the first tooth. Another complete revolution is then again given to the handle, and another space is cut, and of course another tooth is formed, and so on, with a rapidity and precision which is truly astonishing. And by giving to the several cut-

Machinery.

Manufac-
tures.

ters on the cutting wheel their proper figure, the working form of the tooth is at once obtained, which is a great advantage, for where this is left to be wholly effected by the file, it is impossible to arrive at that perfect regularity and uniformity of figure given in this way by the cutter.

In the above description, we have supposed the engine employed in cutting a common toothed wheel; and the reader must suppose the wheel placed vertically on its axis, with its face towards the cutters, these also running vertically, but at right angles to the face of the wheel, and so opposed to its lower circumference, as to cut the tooth of the proper or intended depth; but when a bevelled wheel is to be cut, the frame which supports the wheel is so formed as to admit of giving to the tooth any required inclination or bevel. The Machinery for effecting this is necessarily rather complicated, but it is so admirably executed that it works with the greatest accuracy and by means of proper graduations; it is set to any degree of inclination without a moment's consideration from the workman, beyond that of merely inquiring the number of teeth, their depth, and degree of bevel. It will of course have been understood, although not stated, that the cutting frame is adjustable, so as to operate upon wheels of every variety of diameters, from the largest to the smallest size employed in every description of Machinery.

Engine for
cutting key
ways.

(339.) The teeth being formed, and the wheel removed, a key way is generally required for keying the wheel upon its shaft. This is commonly effected by a cold chisel, and finished with a file; but in this Manufactory the file is but little employed, so that even this operation is performed by means of a cutter, worked by a Machine, which itself receives its motion from the main shaft of the engine. This operation is comparatively simple, as is also the engine by which it is effected. It consists of an upright strong cast iron frame, carrying a cutter or chisel, which descends vertically with great force. The wheel in which the key way is to be cut is placed beneath on a very solid bed, resting on a plate which may be advanced forward by a screw. Every thing being adjusted, so that the cutter in its descent just touches the inside of the hollow axis of the wheel, the latter is slightly advanced, and the cutter or chisel makes its first impression; the chisel now returns, the wheel is again advanced, and in its descent another shaving is removed, and so on, till a key way of the proper dimensions has been formed; by this means all the key ways of the same description of wheel are exactly of the same size, and the key to one will answer for any other. The same exactitude is obtained with all bolts, screws, and nuts, so that the usual precaution of numbering the corresponding parts is quite unnecessary in this establishment.

Hydraulic Engines.

Early hy-
draulic en-
gines.

(340.) Under this head are commonly included all those Machines which are employed in raising water from one level to another, and they are thus distinguished from those which are made to work by the force of moving water. Before the invention and perfection of the steam engine, a number of engines or Machines for the purpose of raising water from low levels, by means of other water descending from a high situation, and which might be discharged at an adit intermediate between the two, were invented, and form a conspicuous figure in our early books of Mechanics and Hydraulics; and even at

this time, when this object can be effected, it will frequently be preferred to steam power, because the power thus gained is obtained at little or no expense; for example, in working a mine, there may be an abundant supply of water at the surface, and at a certain depth an adit may either naturally exist, or may be formed, while a quantity of water may accumulate in the mine at a greater depth. In such a case, the surface water descending to the adit may be competent to work an engine sufficient to raise the lower water to the adit, and, therefore, if the Machinery be not too complicated, the draining may proceed at a very small expense. This, therefore, being the case, it will be proper that we enter in this place into a description of some of the more simple and useful of these engines, and, in particular, those which have not been described in our Treatise on THEORETICAL HYDRAULICS.

Machinery.

It is probable that the earliest mechanical contrivance for raising water was by means of a bucket and axle, as practised to the present day, when only an occasional supply is wanted for domestic or other purposes. This process would soon suggest to an ingenious mind that if two buckets were employed instead of one, the descending empty bucket would in part assist to raise the full bucket. The next step was to arrange a number of buckets, or vessels of some kind, on an endless rope, and then, by giving rotation to the axle, to obtain thereby a constant supply.

First means
of raising
water.

Such means as these are employed to the present day; and in the East, particularly in Egypt, where supplies of water are much required, there are scarcely any other. These Egyptian Machines consist of a number of earthen jars, suspended on an endless rope, which passes round a sort of drum, and when at their highest point, they empty their contents into a trough which carries them to a cistern; the drum is worked by a trundle and cog wheel, and motion is given to it by means of horses, asses, or cows. Something of a similar kind is also still used in Spain, known by the name of the *Noria*. This consists, like the Egyptian Machine, of a series of earthen

Method em-
ployed in
Egypt.

In Spain.

pitchers, connected by ropes, and turned by trundles or pinions, and buckets of wood are sometimes used in a similar manner. A bucket wheel is exactly the reverse of an overshot wheel, and the water here may be raised by buckets nearly similar to those which are calculated for receiving it in its descent in the former Machine. Various constructions are given to this kind of bucket wheel; in this Country a chain is substituted for the rope, and this chain varies considerably in its form and nature. Sometimes the buckets are hung on pins, so as to remain full during the whole ascent, but they are not very generally used, being liable to derangement, and to get out of repair. Sometimes instead of the reversed overshot wheel a reversed undershot wheel is used, or rather the breast wheel; in these cases the floats are worked by wind-mills, and are employed as a throwing wheel. These are most commonly confined to the draining of marshes, fens, &c.; the float boards are not placed in the direction which would be the best for an undershot wheel, but on the same principle, so as to be perpendicular to the surface when they rise out of it.

Bucket
wheel.

Instead of a series of buckets connected by a chain, a similar effect is sometimes produced by a simple rope, or a bundle of ropes passing over a wheel above and a pulley below, moving with a velocity of about eight or ten feet in a second, and drawing a certain quantity of

Hair rope
Machine.

Manufac-
tures.

water up by adhesion and capillary attraction. It is probable that the water commonly ascends with about half the velocity of the rope by comparing its relative velocity with that of a little river; but the rules which serve for computing the velocity of rivers, do not perfectly agree in this case with the results of direct experiments, for the friction required for elevating the quantity raised by such a Machine, appears by calculation to correspond to a velocity about twice as great as the actual relative velocity. While the water is principally supported by the resistance of the rope to its motion, its own adhesion is amply sufficient to prevent its wholly falling or being scattered by any accidental inequality of motion. This Machine being commonly composed of rope made of horse hair, is generally spoken of under the denomination of the *hair rope Machine*.

Archime-
des's screw,
&c.

Another method of raising water, which is frequently employed in excavations for docks, basins, &c., is the spiral pump; this consists of a system of spiral pipes placed on the plane of a wheel receiving the water at its circumference, and raising it by degrees, as the wheel turns, towards the axis, where it is discharged, the motion of the wheel being usually derived from steam or horse power; but the height to which the water is raised by this Machine, is very small in proportion to its bulk. A single pipe wound spirally round a cylinder, which revolves on an axis in an oblique situation, has been denominated the Screw of Archimedes, and is called in Germany the water snail. Its operation is like that of the flat spiral, and may be easily conceived by imagining a flexible pipe to be laid on an inclined plane, and its lower part to be gradually elevated, so that the fluid in the angle or bend of the pipe may be forced to rise; or by supposing a tube, formed into a hoop, to be rolled up the same plane, the fluid being forced, by the elevation of the tube behind it, to run as it were up hill. This instrument is sometimes made by fixing a spiral partition round a cylinder, and covering it with an external coating, either of wood or of metal; it should be so placed with respect to the surface of the water as to fill in each turn one half of a convolution, for when the orifice remains always immersed, its effect is much diminished. It is generally inclined to the horizon in an angle of between forty-five and sixty degrees; hence it is obvious that its utility is limited to those cases in which the water is only to be raised to a moderate height. The spiral is seldom single, but usually consists of three or four separate coils forming a screw, which rises slowly round the cylinder.

German
snail.

The *German snail* is an apparatus of nearly the same kind; it consists of a cylinder with its spiral projections detached from the external cylinder or coating within which it revolves. This Machine may be not improperly considered as a pump, but its operation is precisely similar to that of the screw of Archimedes. It is evident that some loss must here be occasioned by the want of perfect contact between the screw and its cover; and in general one-third of the water runs back, and the Machine cannot be placed at above thirty degrees of elevation. It is, moreover, easily clogged by accidental impurities in the water, yet it has been found to raise more water than Archimedes's screw, but it is more commonly employed on the Continent than in this Country.

Spira-
l pump.

When a spiral pipe, consisting of many convolutions arranged either in a single plane, or in a cylindrical or conical surface, and revolving round a horizontal axis, is connected at one end by a water-tight joint with an as-

cending pipe, while the other receives during each revolution nearly equal quantities of air and water, the Machine is called a spiral pump. It was invented about the year 1746 by Andrew Wirtz, a pewterer at Zurich, and is said to have been used with great success at Florence and in Russia; it was also employed in this Country by Lord Stanhope, and has been made to raise water to the height of forty feet by the late Dr. Young.

The end of the pipe is furnished with a spoon, containing as much water as will fill half of the coil, which enters the pipe a little before the spoon has arrived at its highest situation, the other half remaining full of air, which communicates the pressure of the column of water to the preceding portion; and in this manner the effect of nearly all the water in the wheel is united, and becomes equivalent to that of the column of water, or of water mixed with air in the ascending pipe.

The air nearest to the joint is compressed into a space much smaller than that which it occupied at its entrance, so that where the height is considerable, it becomes advisable to admit a larger portion of air than would naturally fill half the coil, and this lessens the quantity of water raised, but it lessens also the force required to turn the Machine. The joint ought to be conical so that it may be tightened when it becomes loose, and the pressure ought to be removed as much as possible. The loss of power, supposing every thing well constructed, arises only from the friction of the water along the pipe, and the friction of the wheel on its axle; and where a quantity of water has to be raised to a moderate height, both of these resistances may be rendered inconsiderable, but when the height is very great the length of the spiral must be increased, so that the weight of the pipe becomes extremely cumbersome and causes a great friction on the axle as well as strain upon the Machinery. Thus for a height of forty feet, Dr. Young found that the wheel required above one hundred feet of pipe, which was three-quarters of an inch in diameter; and more than one half of the pipe being always full of water, it was necessary to overcome the friction of above eighty feet of such a pipe, which requires twenty-four times as much excess of pressure to produce a given velocity as if there were no friction. The centrifugal force of the water in the wheel would also materially impede its ascent if the velocity were considerable, since it would be always possible to turn it so rapidly as to throw the whole water back into the spoon. It appears that the Machine more particularly alluded to above, which was constructed for Dr. Young did not answer its purpose, or was not found so efficient as was expected of it, for it having got out of repair, this Philosopher thought it more eligible to replace it by a common forcing pump. But he observes, if the wheel and its pipes were entirely made of wood it might in many cases succeed better; or the pipes might be made of copper tinned, or even of earthen-ware, which would be cheaper and lighter than lead.

It has been stated that besides these simple Machines described above, and the various forms of pumps which have been from time to time invented, some of which will be described in a subsequent page, several very ingenious but rather complex engines have been contrived in which water is the moving power, as well as the body raised; that is, the fall of a body of water from a high level, which discharges itself at a certain adit, is made to raise water from a low level to that of the adit. We do not think, however, that it would be advisable to

Machinery.

Manufac-
tures.

engage the reader's attention with a description of the several curious contrivances of this kind which are rather local than general, and many of them more ingenious than useful, beside the most valuable of them have been already illustrated in our *Theoretical Treatise on HYDRAULICS*. We shall therefore in this place confine our description to only one of them which was some few years back erected at one of our Cornwall mines.

Pressure
engine.

Pl. xxvii.
Fig. 1.

(341.) *Pressure engine*.—This is an invention of the late ingenious Mr. Trevethick, but in principle it does not greatly differ from other Machines executed in France many years back, and described by Belidor in his *Arch. Hydraul.* lib. iv. ch. i. Mr. Trevethick's engine, however, is more complete, and is very ingenious; it was first employed at the Druid copper mines in the parish of Illogan near Truro. This engine is represented in plate xxvii. fig. 1, where A B is a pipe six inches in diameter, through which water descends from the head to the place of its delivery, to run off at the adit S through a fall of thirty-four fathoms in the whole; that is to say, in a close pipe down the slope of a hill two hundred fathoms long, with twenty-six fathoms fall, then perpendicularly six fathoms, till it arrives at B, and thence through the engine from B to S two fathoms. At the turn B the water enters into a chamber C, the lower part of which terminates in two brass cylinders *a* and *b*, in which two plugs or pistons of lead D and E are capable of moving up and down by their piston rods, which pass through a close packing above, and are attached to the extremities of a chain leading over and properly attached to the wheel Q, so that it cannot slip.

The leaden pieces D and E are cast in their places, and have no packing whatever. They move very easily, and if at any time they should become loose, they may be spread out by a few blows with a proper instrument, without taking them out of their places. On the sides of the two brass cylinders, in which D and E move, there are square holes communicating towards F and G, which is a horizontal trunk or square pipe, four inches wide and three inches deep. All the other pipes, G, G, and R, are six inches in diameter, except the principal cylinder wherein the piston H moves; and this cylinder is ten inches in diameter, and admits a nine-foot stroke. The piston rod works through a stuffing box above, and is attached to M N, which is the pit rod, or a perpendicular piece divided into two, so as to allow its alternate motion up and down, leaving a space between without touching the fixed apparatus or great cylinder. The pit rod is prolonged down into the mine, where it is employed to work the pumps, or if the engine were applied to millwork or any other use, this rod would form the communication with the first mover.

K L is a tumbler or tumbling-bob, capable of being moved on the gudgeons V from its present position to another, in which the weight L shall hang over with the same inclination on the opposite side of the perpendicular, and consequently the end K will then be as much elevated as it is now depressed.

The pipe R S has its lower end immersed in a cistern, by which means it delivers its water without the possibility of the external air introducing itself; so that it constitutes a Torricellian column or water barometer, and renders the whole column from A to S effectual; as will be seen in the following view of the operation.

The operation.—Let us suppose the lower bar K V of the tumbler to be horizontal, and the rod P O so

situated that the plugs D and E shall lie opposite to each other, and stop the water way G and F. In this state of the engine, though each of these pistons is pressed by a force equivalent to more than a thousand pounds, they will remain motionless, because these actions being contrary to each other, they are constantly in equilibrio. The great piston being here shown as at the bottom of its cylinder, the tumbler is to be thrown by hand into the position delineated in the figure. Its action upon O P, and consequently upon the wheel Q, draws up the plug D, and depresses E so that the water way G becomes open from A B, and that of F to the pipe R; the water consequently descends from A to C, thence to G G G, until it acts beneath the piston H. This pressure raises the piston, and if there be any water above the piston, it causes it to rise and pass through F into R. During the rise of the piston (which carries the pit rod M N along with it) a sliding block I, fixed to this rod, is brought into contact with the tail K of the tumbler, and raises it to the horizontal position, beyond which it oversets by the acquired motion of the weight L. The mere rise of the piston, if there were no additional motion in the tumbler, would only bring the two plugs D and E to the position of rest, namely to close G and F, and then the engine would stop; but the fall of the tumbler carries the plug D downwards quite clear of the hole F, and the other plug E upwards quite clear of the hole G. These motions require no consumption of power, because the plugs are in equilibrio, as is above observed.

In this new situation the column A B no longer communicates with G, but acts through F upon the upper part of the piston H and depresses it; while the contents of the great cylinder beneath that piston are driven out through G G G, and pass through the opening at E and R. It may be observed, that the column which acts against the piston is assisted by the pressure of the atmosphere, rendered active by the column of water hanging in R, to which that assisting pressure is equivalent, as already noticed.

When the piston has descended through a certain length, the slide or block at T upon the pit rod applies against the tail K of the tumbler, which it depresses, and again oversets; producing once more the position of the plugs D E. delineated in the figure, and the consequent ascent of the great piston H, as before described. The ascent produces its former effect on the tumbler and plugs; and in this manner it is evident that the alternations will go on without limit, or until the manager shall think fit to place the tumbler and plugs D E in the position of rest; namely, so as to stop the passage F and G.

The length of the stroke may be varied by altering the positions of the pieces T and I, which will shorten the stroke the nearer they are together; as in that case they will sooner alternate upon the tail K.

As the sudden stoppage of the descent of the column A B, at the instant when the two plugs were both in the water way, might jar and shake the apparatus whose plugs are made half an inch shorter than the depth of the side holes, so that, in such case, the water can escape directly through both the small cylinders R, this gives a moment of time for the generation of the contrary motion in the piston and the water G G G, and greatly deadens the concussion which might otherwise be produced. Some former attempts to make pressure engines upon the principle of the steam engine

Machinery

Manufac-
tures.

have failed; because water not being elastic, could not be made to carry the piston onwards a little so as completely to shut one set of valves and open another. In the present judicious construction, the tumbler performs the office of the expansive force of steam at the end of the stroke.

It has been suggested, as a considerable improvement, that the action of this engine should be made elastic by the addition of an air chamber, on the same principle as that used in fire engines: this, it was thought, might be best effected by making the piston hollow, with a small orifice in the bottom, and of a larger size, to serve for this purpose, as the spring of air would then act both on the upward and downward pressure of the water. We are not aware, however, that this suggestion has been adopted. Gregory, *Mechanics*.

Hydraulic
ram.

(342.) In our Theoretical Treatise on HYDRODYNAMICS an ingenious application of a running stream for the purpose of raising water has been described under the denomination of the Hydraulic Ram. It is only referred to again in this place for the sake of arrangement, and to avoid the necessity of referring the reader to the volume in question. The effect is here produced by the momentum of a stream of water flowing through a long pipe. The passage of the pipe being stopped by a valve, which is raised by the stream as soon as its motion becomes sufficiently rapid, the whole column of fluid must necessarily concentrate its action almost instantaneously on the valve; and in this manner it loses the characteristic property of hydraulic pressure, and acts as if it were a single solid, so that supposing the pipe to be perfectly elastic and extensible, the impulse must overcome any pressure, however great, that might be opposed to it; and if the valve open into a pipe leading to an air vessel, a certain quantity of the water will be forced in, so as to condense the air more or less rapidly, to the degree that may be required for raising a portion of water contained in it to any given height. The first application of this ingenious idea is due to an Englishman of the name of Whitehurst; it was afterwards improved by Mr. Boulton. It was again reinvented or copied by some French engineers, and lastly, was brought out under a new character, and with all the parade of a new discovery, by Mr. Mongolfier, the ingenious inventor of the rarefied air balloon.

It has been stated above, that hydraulic engines are very numerous, and of various forms and construction; but we do not think it would be advantageous to the reader to engage his attention, and to occupy our pages and plates with a description of them; they are frequently fitted to answer particular purposes, and do not admit of general application; they are, moreover, superseded in most cases by the steam engine, which is of general application. A few references, however, to Works in which they are described may be useful; we therefore give the following as the best authorities.

Pumps.

(344.) *Pumps*.—Of all hydraulic engines the pump is

the most common and the most varied in its form; indeed, Machinery the term pump has not uncommonly been extended to hydraulic engines of all descriptions; but the term in its strictest sense is to be understood only of those Machines in which the water is raised by the action of a piston working in a case or cylinder, either on the principle of pressure or suction.

(345.) The theory of both kinds of pumps has been already given in our Treatise on HYDRODYNAMICS; our business here, therefore, is only with their practical application and construction. The simplest kind of pump is that which is worked by a solid plunger; but it requires to have a double barrel to make it advantageous, and is then most applicable to raising water only to small heights. It has been made by fitting two upright beams or plungers of equal thickness throughout into cavities nearly of the same size, allowing them only sufficient room to move without friction, and connecting the plungers by a horizontal beam moving on a pivot. The water being admitted during the ascent of each plunger by a large valve in the bottom of the cavity, it is forced, when the plunger descends, to escape through a second valve in the side of the cavity, and to ascend by a wide pipe to the level of the beam. The plungers ought not to be in any degree tapered, because of the great force which would be unnecessarily consumed in continually throwing out the water with great velocity as they descend, from the interstice formed by their elevation. This pump may be worked by a labourer walking backwards and forwards, either on the beam, or on a board suspended below it. By means of an apparatus of this kind, described by Professor Robison, an active man, loaded with a weight of thirty pounds, has been able to raise 580 pounds of water every minute to a height of eleven feet and a half, for ten hours a day, without fatigue; this is the greatest effect produced by a labourer that has ever been correctly stated by any author; it is equivalent to somewhat more than eleven pounds raised through ten feet in a second, instead of ten pounds, which is a fair estimate of the usual force of a man, without any deduction for friction.

It is obvious that if the plungers were so well fitted to the cavity as to prevent the escape of any water between them, the ascending pipe might convey the water to any required height. The engine would then become a forcing pump, and the plungers might be shortened at pleasure, so as to assume the form of a piston sliding within a barrel. The piston might also be situated above the level of the reservoir, and in this case the water would be forced up after it by the pressure of the atmosphere to the height of about thirty feet, but not much further; and even this height would be somewhat too great for practice, because the water might sometimes follow the piston in its ascent too slowly. Such a pump partakes of the nature of a forcing and sucking pump, and is called a mixed pump. In Delahire's pump, the same piston is made to serve a double purpose, the rod working in a collar of leathers, and the water being admitted and expelled in a similar manner, above and below the piston, by means of a double apparatus of valves and pipes.

(346.) For forcing pumps of all kinds, the common piston, with a collar of loose and elastic leather, is preferable to those of a more complicated structure; the pressure of the water on the inside of the leather makes it sufficiently tight, and the friction is inconsiderable. In some pumps the leather is omitted, for the sake of simplicity,

Simple
forcing
pump.

Manufac-
tures.

the loss of water being compensated by the greater durability of the pump; and this loss will be the smaller in proportion as the motion of the piston is more rapid.

Simple
sucking
pump.

In the common sucking pump, the valve through which the water escapes is placed within the piston itself, so that the same barrel serves for the ascent of the water, which rises in one continued line while the piston is raised, and rests on the fixed valve while it is depressed. The velocity of the stroke ought never to be less than four inches in a second, nor greater than two or three feet; the stroke should also be as long as possible, in order to avoid unnecessary loss of water during the descent of the valve. The diameter of the pipe, through which the water rises to the barrel, ought not to be less than two-thirds of the diameter of the barrel itself.

A bag of leather has also been employed for connecting the piston of a pump with the barrel, and in this manner nearly avoiding all friction; but it is probable that the want of durability would be a great objection to such a Machine.

Where the height through which the water is to be raised is considerable, some inconvenience might arise from the length of the barrel through which the piston rod of a sucking pump would have to descend, in order that the piston might remain within the limits of atmospheric pressure. This may be avoided by placing the movable valve below the fixed valve, and introducing the piston at the bottom of the barrel. Such a Machine is called a lifting pump; but in common with other forcing pumps, it has the disadvantage of thrusting the piston before the rod, and thus tending to bend the rod, and produce an unequal friction on the piston, while in the sucking pump the principal force always tends to straighten the rod.

The rod of a sucking pump may also be made to work in a collar of leather, and the water may be forced through a valve into an ascending pipe. By applying an air vessel in this, or to any other forcing pump, its motion may be equalized and its performance improved; for if the orifice of the air vessel be sufficiently large, the water may be forced into it during the stroke of the pump, with any velocity that may be required, and with little resistance from friction, while the loss of force, from the frequent acceleration and retardation of the whole body of water in a long pipe, must always be considerable. The condensed air reacting on the water expels it more gradually, and in a continual stream, so that the air vessel has an effect analogous to that of a fly wheel in Mechanics.

The pipes through which water is raised by pumps of any kind ought to be as short and as straight as possible; thus, if we had to raise water to a height of twenty feet, and to carry it to a horizontal distance of one hundred feet by means of a forcing pump, it would be more advantageous to raise it first vertically into a cistern twenty feet above the reservoir, and then to let it run along horizontally, or find its level in a bent pipe, than to connect the pump immediately with a single pipe carried to the place of destination. And for the same reason a sucking pump should be placed as nearly over the well as possible, in order to avoid a loss of force in working it. If very small pipes are used, they will much increase the resistance by the friction which they occasion.

(347.) Water has sometimes been raised by stuffed

cushions or by oval blocks of wood, connected with an endless rope, and caused by means of two wheels or drums, to raise in succession in the same barrel, carrying the water in a continual stream before them; but the magnitude of the friction of the cushions appears to be an objection to this method. From the resemblance of the apparatus to a string of beads, it has been called a bead pump, or paternoster work. When flat boards are united by chains, and employed instead of these cushions, the Machine may be denominated a cellular pump; and in this case the barrel is usually square, and placed in an inclined position, but there is a considerable loss from the facility with which the water runs back. The chain pump generally used in the Navy is a pump of this kind, with an upright barrel, through which leathers, strung on a chain, are drawn in constant succession; these pumps are only employed when a large quantity of water is to be raised, and they must be worked with considerable velocity, in order to produce any effect at all. An improved construction of the chain pump, so as materially to increase the quantity of water raised by it, is described in a subsequent article.

(348.) It is frequently necessary to procure alternate motion in pumps by means of wheelwork; and for this purpose the application of a crank is the most usual, and perhaps the best method. Provided that the bar by which it acts be sufficiently long, very little will be lost by the obliquity of its situation, and it is easy, by means of rollers, or of a compound frame, to confine the head of the pump rod to a rectilinear motion. When any other mode is employed, it must be remembered that the motion of the pump rod ought always to be slower at the beginning of each alternation, since a considerable part of the force is consumed in setting the water in motion, especially where the pipe is long and the velocity considerable. But it may happen that, from the nature of hydraulic pressure under other circumstances, the resistance may be nearly equal throughout the stroke; for example, when the motion of the piston is slow, in comparison with that of the water in the pipe, or when the force employed in producing velocity is considerable in comparison with that which is required for counteracting the pressure. In such cases it may sometimes be eligible to employ inclined surfaces, of such forms as are best adapted to communicate the most advantageous velocity to the pump rod by their pressure on a roller, which may be confined to its proper direction by the same means as when a crank is used. The Chinese work their cellular pumps or bead pumps by walking on bars which project from the axle of the wheel or drum that drives them, something after the manner of our tread-mill; and whatever objection there may be to the pump itself, the mode of communicating the motion to it must be allowed to be ingenious and advantageous.

Pumps have sometimes been worked by means of the weight of water acting within a barrel, which resembles a second pump placed in an inverted position; this is somewhat similar to the engine described in the preceding article under the denomination of the Pressure Engine, by Trevethick, the principle of which, as we have stated, is very nearly the same with that described by Belidor, and known in Germany under the name of Hüll's Machine.

(349.) Amongst other ingenious ideas connected with the subject of raising water, we ought to mention that which has been suggested for effecting this object by the spontaneous vicissitudes of the pressure of the air, occasioned

Raising
water by

pressure in
the atmo-
sphere.

Machinery.

Paternos-
ter work.

Pumps
worked by
cranks.

Manufactures.

by changes in the weight and temperature of the atmosphere by means of a series of reservoirs furnished with proper valves. But it seldom happens that such changes are capable of producing an elevation of water in each reservoir of more than a few inches, or at most a foot or two in a day, and the whole quantity raised, therefore, must be very inconsiderable.

Centrifugal pump.

(350.) Another hydraulic engine commonly considered to belong to this class, is the centrifugal pump. This is the reverse of Barker's mill. It consists of a vertical pipe, caused to revolve round its axis, and connected above with a horizontal pipe, which is open at one or at both ends, the whole being furnished with proper valves to prevent the escape of the water when the Machine is at rest. As soon as the rotation becomes sufficiently rapid, the centrifugal force of the water in the horizontal pipe causes it to be discharged at the end, its place being supplied by means of the pressure of the atmosphere on the reservoir below, which forces the water to ascend through the vertical pipe. It has also been proposed to turn a Machine of this kind by the counterpressure of another portion of water, where there is fall enough to carry it off. This engine may be so arranged, that, according to theory, little of the force applied shall be lost; but it has failed of producing in practice a very advantageous effect.

Having given above a concise account of the more simple description of pumps and the principles on which they act, it remains now for us to describe some peculiarities introduced into the mechanism by which these principles are brought into action.

Taylor's sucking pump. Pl. xxviii. Fig. 1.

(351.) In the course of the preceding observations, reference has been made to different ways of working the piston, and the following has been much recommended for the little friction it produces. Plate xxviii. fig. 1, is a vertical section of this pump. The piston rods have racks at their upper parts working on the opposite sides of a pinion and are kept to their proper position by friction rollers. The valves used in this pump are of three kinds, as shown at *a, b, c*. The former is a spheric segment which slides up and down on the piston rod, and is carried down by its own weight; the second *b* is called the pendulum valve; and the third *c* is a globe which is raised by the rising water, and falls again by its own weight. Each of these valves will disengage itself from the chips and gravel, &c. brought up by the water. In this kind of pump the piston may be put in motion by a handle in the usual way, or a rope may pass round the wheel *d e* in a proper groove, the two ends of which, after crossing at the lower part of the wheel, may be pulled by one or more men on each side. A pump of this kind, of seven inches bore, is said to be capable of lifting a ton of water to the height of twenty-four feet in a minute when worked with ten men, five on each side.

Stephens's forcing pump.

(352.) A forcing pump of a very ingenious description is represented in plate xxvii. Here fig. 2 is the section of a well in which a pump of this kind is fixed. A A represent the surface of the ground, and B B the brick-work of the well, in which the water stands at the level C, and is, by the pump, to be raised to the surface A A.

D is a lever or handle of the pump, which has the part *a* jointed to it and descending to the pump; the rod is made of wood, in several lengths, which are united by joints of iron, in the manner shown in fig. 3, the wooden rods *a a* being capped with iron forks *b*, which include the ends of them, and are rivetted fast; the ends of the forks are jointed together to connect the

several lengths. E is the working barrel or chamber of the pump, in which the bucket *d* works; this path is formed of a tree, bored through, and having a projecting branch *e*, which is likewise bored obliquely to the barrel, and forms the forcing pipe; in the bottom of the barrel the suction valve *f* is situated, being at the top of the suction part of the pump, which is bored with a smaller auger than the working chamber, which is also lined with a brass tube where the bucket works. The top of the barrel is covered by a metal lid *g*, (see also fig. 4 and 5,) which has a stuffing box in the centre to receive the metal cylindrical part of the pump rod *h*; to the lower extremity of this the bucket *d* is fixed. The metal lid consists of a ring, which is screwed to the wooden barrel by five screw bolts, passing through as many ears, projecting from the circumference of the ring; they have eyes below to hook upon pins, which are fixed in the wood, but project sufficiently for these bolts to hold the ring firmly down, by means of nuts screwed upon them. The movable lid of the pump, which has the stuffing box *g* formed in the centre of it, is screwed to the ring by five screws, and these can be taken out to remove the lid, and draw up the bucket when it requires to be leathered.

F is the forcing pipe, formed of as many pieces of wooden pipes as are required to make up the length; they are united together by making the upper ends conical, to enter a similar cavity made in the lower end of the next pipe; the lowest piece fits upon the extremity of the projecting branch *e*, and a valve is proposed to be put in the pipe, at this joint, to prevent the return of the water, and bear part of the weight of the column from the lowest valve at *f*; the upper length of the pipe has a spout *i* at which the water is delivered.

N is a second spout fixed into the pipe lower than the former; it has a screw by which it can be united to a hole, or leathern pipe, to convey the water to a distance, or by means of a jet or branch pipe to throw it in the manner of a fire engine; in this case the upper spout *i* must be stopped up by a screw plug or cap; and there is a copper air-tight vessel H situated at the top of the pipe F, to equalize the pulsative motion of the water as thrown by the pump.

k is a bracket fixed to the pipe F, and projecting over the centre of the pump, where it has a hole to receive the pump rod *h*, and guide it steadily in its motion up and down, that it may not wear the stuffing box away on one side. As the wooden tubes of which the forcing pump F is composed, may be made from waste or crooked timber, it makes a great difference between the low price of such, and that of the straight trees necessary for common pumps.

A wooden plug may be chained to the pump betwixt the spouts or nozzles M and *i*, so as to be ready to stop that which is not wanted in use.

Mr. Stephens is of opinion, that it is better to place the valve *f* above the level of the water in the well. *Society of Arts*, vol. xxxii.

(353.) Hedderwick's double piston pump.—The general character of double piston pumps is to have the piston rods attached to one side of the pistons, which has a tendency to give an unequal pull upon them, whereas in this contrivance they are attached to the centre of the piston, the lower piston rod passing through the centre of the upper piston.

The method of doing this is more particularly shown

Hedderwick's double piston pump.

Manufactures. in fig. 2, 3, and 4, pl. xxviii. In fig. 3, K K, D D, is part of the piston rod of the other piston with two branches D D joined at D D to the piston F F.

Pl. xxviii. Fig. 2, 3, 4. G G is part of the piston rod of the lower piston, passing through the cross bar F F, which is attached to the top of the upper piston; E E is another cross bar by which the piston rod G G passes.

The joined pistons here shown are only necessary in large pumps. In smaller ones, the joint D and the bar E E may be dispensed with, and thus the piston rod may be all in one piece, fastened to the top of the piston box at F F, the pliancy of the rods rendering the joint at D needless.

Fig. 4 represents the top of the piston with the cross bar F F, through which the lower piston rod G G, fig. 3, passes. The two valves are formed of one piece of leather in the usual manner, which is confined under the bar or cross piece F F, and is strengthened by having two plates of iron rivetted upon it, one on each valve, the valves being what are usually termed butterfly valves.

The principle of action will appear from the manner of working the pump as follows:

In fig. 2, A D H is a handle or bent lever upon one side, and L K I is a similar one on the other side of the pump, by which the power is communicated to the pistons; the lever A D H is movable round the fulcrum or centre D, and the lever L K I round the centre K; the extremities I and H are connected by a bar I H, so that when the end of the one lever A is depressed, the other is raised; the parts A D and L K of the levers are continued to E and O beyond their centres of motion D and K, so as to be as nearly over the centre of the bore of the pump as possible, but free of each other in the operation of working.

By this connection, when the handle A is depressed, the handle L is raised, the piston G is depressed, and the other piston F raised. This motion being reciprocally continued, gives a double advantage in lifting the water; for, when the one handle is pulled down, the piston attached to that handle is raised, and when the same handle is raised up, the piston belonging to the opposite handle is also raised.

From the construction of this pump with two pistons, it appears evident that the pump barrel would raise twice as much water in the same time as two others of equal bore with one piston each; a benefit of sufficient importance in many cases of accidents at sea. But upon a comparative trial before the Committee of Mechanics appointed by the Society of Arts, (to which the plan was submitted by the inventor,) it turned out that the pump with two pistons actually raised twice and a half as much water as another pump with one piston only, which was connected with it so as to make equal strokes therewith, did in the same time; a difference in favour of the pump with two pistons so remarkably great, as to occasion doubts in the minds of the Committee whether the pistons or bore of the double piston pump might not have been more accurately formed than in that with a single piston. On this account they shifted the pistons from the one barrel to the other, but, on repeating the experiment, the result was the same as before; a convincing proof that the experiment was a fair one. And, in fact, the difference in the effect of the two pumps can be perfectly well accounted for by the consideration that in the pump with a single piston, the water, after being put into motion by the action of the

Machinery. pump, is suddenly stopped by the change of motion during the descent of the piston, and has to be again put into motion at every stroke of the pump, to the great hinderance of the regular discharge of the water; whereas in the pump with two pistons the flow from it is nearly continual during its action, the one piston constantly ascending whilst the other is descending, and the momentum of the water continuing its ascent during the change of motion in the pistons, and thus producing the very great difference in favour of the performance of the pump with two pistons; neither does this pump ever require double the force that is applied to one with a single piston to work it, it being much easier to continue a motion when commenced, than to renew it perpetually when interrupted, as it is in the pumps with one piston only.

(354.) *Franklin's double piston pump.*—This Machine Franklin's double piston pump. also is one presented to and rewarded by the Society of Arts. See *Trans.* vol. xxxiii. Here A A are two pistons, on the upper surface of each is a double valve, v v v v; the upper piston passes through the stuffing box B, and the lower through the stuffing box C; S is the suction pipe, and D the discharging pipe.

Fig. 7 is an external view of the pump; e e e the lever or handle; F the fulcrum, on which the handle moves; G G the pump cylinder; W W the wheels which revolve between the standards X X, and which conduct the piston rods parallel to the cylinder; e P the conducting rod which conveys the motion of the handle to the lower piston; e O the conducting rod which gives motion to the upper piston. It is evident when the handle or lever is lifted, that the upper piston is pressed down, and the lower piston is at the same time elevated, and its valves shut, which forces the water through the upper piston and the discharging pipe at the same operation. And when the handle is pressed down, the upper piston rises with its valves closed, and the water, in its ascension, is forced through the discharging pipe; at the same time, the lower piston descends, by which action its valves are opened, and introduces a supply of water equal to the contents of the cylinder, minus the capacity of both pistons. The peculiar advantages of this pump with double pistons are, that with a six-inch stroke it discharges a quantity of water equal to twelve inches of the cylinder; and so, in this proportion, by always doubling the quantity of the stroke, whatever it may be; and thus furnishing a product just equal to two common pumps of the same stroke and capacity of cylinder, and certainly with less than a proportionable friction and expense. Fig. 6 is an enlarged section of the cylinder G G, fig. 7, showing the valves V V.

(355.) *Pumps for ships.*—When the desperate consequences attending the gradual sinking of a vessel at sea which has sprung a leak are considered, it will be readily admitted that a good ship pump is an engine of the utmost importance, and that too much care and attention cannot be paid to rendering it effective and powerful. It is not therefore extraordinary to find that almost every description of pump has been tried on shipboard; but that which seems to have been preferred is the chain pump, of which there are still some varieties; but beside the chain pumps, all ships in the British Navy are supplied with hand pumps. The larger class of ships of war have four of the former, and three of the latter class, all communicating with one well: one of the hand pumps, called the wash deck pump, being used to raise water from a cistern in the hold to the

Manufac-
tures.

upper deck for the purposes of washing the decks; but it is also applicable on emergency for pumping the ship. Several kinds of hand pumps have been proposed for this purpose, the first of any notoriety having been the invention of Benjamin Martin, the well-known author of several ingenious popular Works on Philosophical and Mathematical subjects.

Smeaton's
ship pump.

(356.) Mr. Smeaton also projected a pump for this purpose which is described in the first volume of his *Reports*. He there observes that the common ship pump generally delivers its water upon the main deck, which, according to the size and construction of the ship, is four, five, or more feet above the surface of the ocean, or load water line, while this line itself is not more than from 14 to 18 feet above the ship's bottom; consequently the common pump lifts the water one-third or one-fourth higher than is necessary. He proposed, therefore, wooden trunks or pipes, proceeding horizontally from the upright trunk of the pump, to carry off the water through the ship's side, and fitted at the other end into bores or short working tubes, just above the said line. These side pipes to be closely jointed with the boxes in the ship's side at one end, and at the other end into strong planks bolted against the sides of the pump, in order that the side pipes might be got out and in without disturbing the pump, which was of the sucking kind, its piston or bucket having been worked by a lever or brake upon the deck over the pump itself. From its top a stand pipe was carried up to the main deck, or as high as was thought necessary, to prevent the water reverting and returning back into the ship over the top of the pump, when the sea rose above the orifices of the side pipes, or when, from the ship being in distress, they were under her load water line. By this means, when even both boxes and pipes were under water, it would in no way interrupt the action of the pump, for whenever the water in the stand pipe rose above the level of the water without, the pressure of the column in the stand pipe would cause it to make its way through the side pipes, so that in this case no level was lost, and, although the pump should be at rest, no water could revert down the pump, because there were both bucket and fixed box, or clack, which prevented it. The working barrel was of brass, and very truly bored; both the bucket and fixed box having been of the same construction as those used in steam engines—or, as Smeaton always denominated them, fire engines—and the pump rod was made of greater bulk than was necessary, merely for strength, in order to furnish weight, whereby when the brake was lifted up, the pump rod should readily descend by its own weight. The brake of the pump had a branch fixed on rather obliquely on each side, so as to form three handles for four men to work at one time; these stood one on each side of the middle stem of the brake, and one on the outside of each branch handle, and every quarter of an hour they could relieve themselves by changing hands, which was done by changing places. It was intended that the number of strokes per minute should not exceed twenty-five, the length of each stroke being $17\frac{1}{4}$ inches, and the barrel a nine-inch bore, which was considered to be better than making shorter and quicker strokes, as was the case in the older pumps. The men's hands moved up and down about four feet six inches, and by working with this stroke at a moderate rate, so as to hold it on an hour, four men would in that time deliver 20 tons at a height of 22 feet. This was upon a supposition of

raising the water to the usual height; but when, by the application of the maxim before described, this perpendicular was shortened to 16 or 17 feet, then nearly the same delivery could be made by three men, or proportionably more by four men, that is, as 17:22::20:26 tons at 17 feet. The foot of the pump was let through the ship's inner planking or ceiling, betwixt two of the floor timbers, and did not touch the bottom or outside planking within $2\frac{1}{2}$ inches, with the lower end rounded withinside like a trumpet mouth, it being supposed a bad plan to have the pump standing upon its lower extremity, with holes bored to let in the water, as it is thus very liable to be choked by dirt. A plank of the ceiling was made to lift up near the pump's foot, so that a man could occasionally get in his arm, to clear away any chips, sand, dirt, or other matter which might have accumulated. Representations of this pump, and of all its detached parts, are given in the volume of Smeaton's *Reports* above referred to.

(357.) Another description of hand pump, by Mr. Noble, is very ingenious, but rather too complicated for sea purposes to be a general favourite with seamen. Here are two buckets, working one below the other in the same barrel, which rise and fall alternately, by having the rod of the lower of the two buckets pass down through the upper bucket in a collar of leather, and uniting the rods of the two buckets to the brake or lever on opposite sides of its centre, so that the descent of one causes the elevation of the other, and produce by their joint action a constant stream of water, one bucket being always raising a column while the other is descending for a fresh supply. Such a pump requires no lower valve, unless by way of precaution, in case either bucket should be out of repair, in which case it would become a single pump.

(358.) *Kingston's ship pump*.—This Machine is applicable as well to extinguishing fires on board, as for the usual purposes of pumping: it is commonly called a chest pump, being enclosed in a close case with handles, H H, fig. 5, pl. xxviii. for lifting it from place to place; the handles, when not in use, fall down vertically, occupying thus less room. Two brass cylinders, of four inches bore, are united by proper screws, nuts, and flanches, with the base B, in which is a pipe B communicating with each cylinder. The space around and between the cylinders and the casing of the pump serves as an air chamber, by which the water is kept under compression. The lower connecting pipe B is made to communicate with the supply of water by means of a leathern hose screwed on, at right angles to this section, unto the screw cut on the interior of the tube B, seen in fig. 6, and the eduction pipe is screwed on exteriorly upon the pipe C, fig. 6. The pistons are solid, and the action is obviously that of forcing. In the position of the rods, pistons, &c. shown in the drawing, the piston P has arrived at the top of its stroke, the water following it through the open valve V, while the descent of the other piston P' has forced its water through the valve V'' into the air chamber. On the return stroke the valve V will be shut, and the valve V' will be forced open, while the water in this barrel is being forced into the air vessel. During this the piston P' is elevated, and the water from the communicating pipe B forces open the valve V'', while V' is kept shut by the pressure of the air and water in the chest E. In the mean time the water is thrown out in a continued stream through the eduction pipe when used for common pumping, or

Noble's
ship pump

Kingston's
ship pump.

Manufactures.

through the flexible hose and pipe when used for the purpose of extinguishing a fire. The parallel action of the piston rods is obtained in nearly the same way as in the steam engine, by means of the bridle links I I' connecting the hanging links L L' with the standards G G': the piston acting on a joint in the centre of the hanging links. The brake or handle by which the pistons are worked turns on an axle, supported by the central strong standard F F', which is fixed in its place by being screwed into the base, and passing through a hole in the upper part of the air chamber. Through a hole at the end of the iron handles is fixed a transverse bar, so as to allow as many men to work on each side as may be thought necessary. As the drawing sufficiently illustrates the entire operation of this very simple apparatus, we need only add that the whole is securely screwed down to a wooden frame D D, which serves as a base; the screws by which this is effected being seen in fig. 6, but not in the section, fig. 5.

Jekyl's pump.

(359.) Another pump, which seems to have been considered a very good one, was invented by Capt. Jekyl, R. N., and several of them were introduced into the British Navy; but for some reason they are now seldom applied. Beside this we might enumerate many others, but as they are seldom if ever used, it would be to little advantage to the reader. It may also be observed, that besides the different arrangements above alluded to in the pumps themselves, different methods of working them have also been suggested, by converting the reciprocating motion of the handle into a circular motion, and by converting the up and down motion of the handle into a motion resembling that of rowing, in which a man is generally considered to exert his strength to the best advantage, and particularly a sailor, who is familiar with the rowing motion.

We shall conclude this division by describing the common ship pump and chain pump now generally adopted in the British Navy.

Common ship pump.

(360.) Both of these are remarkably simple. The sucking and lifting pump differs scarcely at all from the common lifting pump, except in the form of its handle, which has a transverse bar for the convenience of employing more than one man. The barrel in which the piston works is three feet long, composed of brass, accurately bored to five inches. The upper part of the piston rod also differs a little from a common pump, by working through a collar of leather, whereby a certain degree of compression may be given to the water, so as to allow of its being worked as a fire engine; when thus employed, a part is added to the common pipe, and held fast on by a clasp hook on each side. On the exterior part is an exterior screw, on which may be screwed the leathern hose when the pump is used for projecting the water to any distance; as in the case of fire, or for any other purpose.

Chain pump. Pl. xxviii. Fig. 8.

(361.) *Chain pump for ships.*—The chain pump, fig. 8, is only a long chain A, with a sufficient number of pistons, called buckets or saucers, fixed upon it at proper distances; it passes downwards through a wooden tube B, and returns upwards in the same manner, on the other side D, the ends being united together. The chain is extended over two wheels E and F, called sprocket wheels; one is placed over the tubes B and C of the pump, and the other at the bottom in the space between the two tubes through which the chain ascends and descends. By turning the upper

wheel E, the chain of buckets is put in motion, and the lower part of the wooden tube in which the chain ascends is lined with a brass barrel, in which the saucers are fitted, and as they continually ascend they raise the water, which runs off from the top of the ascending trunk, and is carried by a trunk through the ship's side into the sea. The pump is worked by a crank or winch G, fixed on the axis of the upper wheel, whereon several men may be employed at once; and thus it discharges, in a limited time, a much greater quantity of water than the common pump, and with less inconvenience to the labourers.

Machinery

The chain pump now in use in the Navy is of a very improved construction, compared with the original chain pump. It was introduced by Mr. Cole, under the direction of Captain Bentinck; its chain is very simple, and not much exposed to damage; being exactly similar to that of the fire engine, and appears to have been first applied to the pump by Mr. Mylne to exhaust the water from the caissons at Blackfriars bridge. It has thence been transferred to the marine by Captain Bentinck, after having received some material additions to fit it for that service.

The links of the chain are each formed of two long plates of iron *ee*, with a hole at each end, and fixed together by two bolts, serving as pins for the joints. The buckets or saucers fixed upon it are two circular plates of brass *g*, with a piece of leather between them. The sprocket wheels for the chain are formed in the same manner as the trundles used in mills, by two iron wheels fixed at eight inches' distance upon their axles, and united by several round iron bolts, forming a rest for the chain; and its links have hooks *b*, which are taken by these bolts, and thus the chain is secured upon the wheel, to prevent it from jerking back when charged with a column of water.

This, as above stated, is a great improvement upon the old chain pump, in which the chain was complicated, and the sprocket wheels used to work it were deficient in wanting some contrivance to prevent the chain from sliding or jerking back upon the surface of the wheel, which frequently happened when the buckets were charged with a considerable weight of water, or when the pumps were violently worked; the links also were too short, and the manner in which they were connected, exposed them to great friction in passing round the wheels; hence they were sometimes apt to break or burst asunder in very dangerous situations, when it was extremely difficult or impracticable to repair the chain.

The present pump is so constructed that the chain may be easily taken up and repaired when broken or choked with ballast; and it discharges a much greater quantity of water with an inferior number of men, as appeared from a trial with it and the old chain pump aboard the Seaford frigate, where it was found that its effects, when compared with the latter, were as follows: the new pump with four men raised one ton of water in forty-three seconds and a half, while the old pump required seven men to raise the same quantity of water in seventy-six seconds.

In this experiment the chain of the new pump was purposely broken and dropped into the well, and afterwards taken up and repaired, and set to work again in two minutes and a half; then the lower wheel of the pump was taken out, to show how readily it might be cleared and refitted for action, after being choked with sand or gravel, which could be performed in four or

Manufac-
tures.

five minutes. These are advantages of equal importance with that of increasing the quantity of water which the Machine will raise.

The only alteration which has been made in this pump since its first introduction is, that the lower sprocket wheel is now omitted altogether, the ascending and descending pipes being so united by a curved metal tube, that the chain passes better than if a wheel were used. The cranks are made to take off and to be applied when wanted, that they may not be in the way; they are long enough for thirty men to work at once: of late it has been proposed to add fly wheels to them. This would be attended with but slight advantage while it would introduce several inconveniences, from occupying that room where the men should stand to work, it being an object to employ as many as possible; but if they are crowded, they only incommode each other instead of assisting.

Fire Engine.

Early his-
tory of the
fire engine.

(362.) The invention of the fire engine appears to be nearly coeval with that of the pump, both being attributed to Ctesibius, who lived in Egypt in the time of Ptolemy Philadelphus and Ptolemy Euergetes; at all events, Hero, who was a pupil of Ctesibius, expressly describes a forcing pump with two cylinders as a Machine applicable to the purpose of extinguishing fires, but it does not appear that it was very generally adopted. That the fire engine was known, although, perhaps, not very generally made use of by the Romans, appears by a letter from Pliny to the Emperor Trajan, in which he announces the destruction of the town of Nicomedia, in Bithynia, by fire, remarking, that the devastation had been increased by a violent storm which took place at the time, by the laziness of the inhabitants, and by the want of Machines or apparatus proper for extinguishing the flames. These Machines are referred to by Pliny under the term *sipho*, which some have maintained means only water pipes; but Beckmann seems to have no doubt that *sipho*, in this place, must have meant a fire engine, and quotes a passage from a fragment of a Work of Apollodorus, the architect to Trajan, which seems decisive of the question: this quotation relates to a method of extinguishing a fire in the upper part of a house when the *sipho* is not at hand, which consisted of filling leathern bags with water, and connecting long pipes to them, so that by compressing the bags the water might be projected to certain heights. However rude this contrivance may be, it shows clearly that, being intended to supply the place of the *sipho*, this latter could have been nothing less than some kind of fire engine. There are, however, strong reasons, from other circumstances, for concluding, that although the fire engine was not unknown to the Romans, it was very little employed, and was most likely invented in much more recent times in Germany without any knowledge of the Roman engine, but at what time it was first introduced into that Country is by no means certain. It is remarked by Von Stetten, that in the building accounts of the city of Augsburg fire engines are first mentioned in the year 1518. They are called there *instruments for fires*, or *water syringes* used at fires; and these names seem to announce that the Machine was then in its infancy. At that time, they were made by a goldsmith at Friedberg, named Anthony Blanter, who, the same year, became citizen of Augs-

burg. From the account added, that the wheels and levers were constructed by a wheelwright, and from the greatness of the expense, there is reason to conclude that these were not small, simple hand engines, but large and complex Machines. Machinery.

In the year 1657, the celebrated Jesuit, Caspar Schott, was struck with admiration on seeing at Nuremberg a fire engine, which had been made there by John Hantsch. It stood on a sledge ten feet long and four feet broad. The water cistern was eight feet in length, four in height, and two in width. It was moved by twenty-eight men, and forced a stream of water an inch in diameter to the height of eighty feet, consequently over the houses. The Machine was drawn by two horses. Hantsch distributed throughout Germany an engraving of it, with an offer of constructing similar ones at a moderate price, and teaching the use of them; but he refused to show the internal construction of it to Schott, who, however, readily conjectured it. From what he says of it, one may easily perceive that the cylinders did not stand in a perpendicular direction, but lay horizontally in a box, so that the pistons moved horizontally and not vertically, as at present. Upright cylinders, therefore, seem to belong to the more modern improvements. Schott adds that this was not a new invention, as there were such engines in other towns, and he himself, forty years before, and consequently in 1617, had seen one, but much smaller, at Königshofen, his native city. George Hantsch, also, son of the above artist, constructed similar engines, perhaps with improvements, for Wagenseil and others have ascribed to him the invention.

The first regulations at Paris respecting fires, as far as is known, were made to restrain incendiaries, who, in the XIVth Century, under the name of *boutefoux*, occasioned great devastation not only in the Capital but in the Provinces. Paris appears to have obtained fire engines, for the first time, in the year 1699; at any rate the King at that period gave an exclusive right to Dumourier Duperrier to construct those Machines called *pompes portatives*; and he was engaged, at a certain salary, to keep in repair seventeen of them, purchased for the city, and to procure and to pay the necessary workmen. In the year 1722, the number of these engines was increased to thirty, which were distributed in different quarters of the city, and at that time the contractors received annually twenty thousand livres.

In the middle of the XVIIth Century, fire engines were still very imperfect. They had neither an air chamber nor buckets, and required a great many men to work them. They consisted merely of a sucking pump and forcing pump united, which projected the water only in spurts, and with continual interruption. Such Machines, on each movement of the lever, experience a stoppage, during which no water is thrown out; and because the pipe is fixed, it cannot convey water to remote places, though it may reach a fire at no great distance, where there are doors and windows to afford a passage. At the same time the firemen are exposed to danger from the falling of the houses on fire, and must remove from them to a greater distance. Hantsch, however, had adapted to his engine a flexible pipe, which could be turned to any side as might be necessary, but certainly not an air chamber, otherwise Schott would have mentioned it. In the time of Belidor there were no other engines in France, and the same kind alone were used in England in 1760.

Manufactures.

Who first conceived the idea of applying to the fire engine an air chamber, in which the included air, by compressing the water, forces it out in a continued stream, is not known. According to a conjecture of Perrault, Vitruvius seems to speak of a similar construction; but Perrault himself acknowledges that the obscure passage in question might be explained in another manner. The air chamber in its action has a similarity to Hero's fountain, in which the air compressed by the water obliges the latter to ascend.

We find no older fire engine constructed with an air chamber than that of which Perrault has given a figure and description. He says it was kept in the King's Library at Paris, and during fires could project water to a great height, that it had only one cylinder, and yet threw out the water in one continued jet. He mentions neither its age nor the inventor; his book was printed in 1684. The principle of this Machine, however, seems to have been mentioned before by Marriotte, who, on this account, is by some considered as the inventor; but he does not appear to have had any idea of a fire engine, at least he does not mention it.

It is certain that the air chamber, at least in Germany, did not come into common use till after it was applied by Leupold to fire engines, a great number of which he manufactured and sold. He gave an account of it in a small Work, consisting of four sheets quarto, which was published in 1720, but at first he kept the construction a secret. The engines which he sold consisted of a strong copper box closely shut and well soldered. They weighed no more than sixteen pounds, occupied little room, and only one cylinder, and a man with one of them could force up the water without interruption to the height of from twenty to thirty feet. About 1725, Du Fay saw one of Leupold's engines at Strasburg, and discovered, by conjecture, the construction of it, which he made known in the *Transactions of the Academy of Sciences, at Paris*, for that year. It is very singular that, on this occasion, Du Fay says nothing of Marriotte, or of the engine in the King's Library. Leupold, however, had some time before, that is in 1724, given a description and figure in his *Theatrum Machinarum Hydraulicarum*, with which, undoubtedly, Du Fay was not acquainted.

Another improvement, no less useful, is the leathern hose added to the engine, which can be lengthened or shortened as necessary, and to which the fire pipe is applied, so that the person who directs the jet of water can approach the fire with less danger. This invention, it is well known, belongs to two Dutchmen, both named Jan Van der Heide, who were inspectors of the apparatus for extinguishing fires at Amsterdam. The first public experiments made with it took place in 1672, and were attended with so much success, that, at a fire next year, the old engines were used for the last time, the new ones being introduced in their stead. In 1677, the inventor obtained an exclusive privilege to make these engines during the period of twenty-five years. In 1682, engines on this construction were distributed in sufficient number throughout the whole city, and the old ones were entirely laid aside. In 1695, there were in Amsterdam sixty of these engines, the nearest six of which were to be employed at every fire; and in the course of a few years they were common throughout all the towns in the Netherlands.

All these circumstances have been related by the inventor in a particular Work, which, on account of the

excellent engravings it contains, is exceedingly valuable. Machinery Of these, the first seven represented dangerous conflagrations at which the old engines were used, but produced very little effect. One of them is the fire which took place in the Stadthouse of Amsterdam in the year 1652. The twelve following plates represent fires which were extinguished by means of the new engines, and exhibit, at the same time, the various ways in which the engines may be employed with advantage. According to an annexed calculation, the city of Amsterdam lost by ten fires, when the old apparatus was in use, 1,024,130 florins; but in the following five years, after the introduction of the new engines, the loss occasioned by forty fires amounted only to 18,355 florins; so that the yearly saving was ninety-eight per cent. Of the internal construction of these engines no description or plates have been given, nor is there any reason to believe they were furnished with an air chamber, though in the patents they were always called *spouting-engines* which threw up one continued jet of water. The account given even of the nature of the pipe or hose is short and defective, probably with a view to render it more difficult to be imitated. It is only said that it was made of leather in a particular manner, and that besides being thick, it was capable of resisting the force of the water. The conducting or feeding hose was also the invention of the same two Dutchmen, the end intended to be placed in the pond or river having been by them inserted in a cork to float it, and its end was defended by a grating or brass plate pierced with small holes to prevent any mud or dirt from entering.

Here then, with the exception of the air vessel, is the completion of the invention of the fire engine, viz. a sucking and forcing pump, some method to preserve a constant stream of water, flexible hose for bringing water from any approachable supply, and a directing pipe furnished also with flexible hose for conducting the jet of water into narrow places into which the engine itself could not be taken. The modern fire engine in principle is no more than this with the addition of an air vessel, but the progress of the Arts has of course added much to the perfection and performance of it in other respects as compared with those of the old construction, and the forms it has undergone have been proportionally numerous. Notwithstanding hose were undoubtedly known on the Continent many years before they were used in England, they were always more or less defective; some were made of canvass covered with a cement to make them water tight, some were woven in the tubular form by looms or Machines made expressly for the purpose, and others were made of leather, which is the material now commonly employed in this Country; and as preserving them always water tight is a matter of some difficulty, several ingenious persons have directed their attention to this object.

One of the most recent improvements in their construction is due to Mr. Perkins, so well known for his many ingenious inventions. The usual method of closing the two edges of the leather to form the hose, was by sewing them together as a shoemaker closes the leather of a pair of boots, but Mr. Perkins recommends that instead of sewing them, the sides should be closed with rivets, indeed the rivet had been before employed for this purpose by Messrs. Hancock and Sellers of Philadelphia, for several years; but Mr. Perkins's operates somewhat differently. He recommends that the leather should be more overlapped, and has invented a method of connecting two

Manufac-
tures.

hose without contracting the water way at the joints. Particulars relative to this improvement will be found in vol. xxxviii. of the *Transactions of the Society for the Encouragement of Arts, &c.* It will be sufficient for us here to give a verbal description of it. The rivets substituted for the usual thread are of copper, and the overlapping of the leather serves when it is wetted as a sort of valve to tighten the seam; and as the portion of the hose next to the engine is found to be the part which most commonly bursts, especially when the water is carried perpendicularly, the first three or four portions are double rivetted, the other part has only a single row, and the different pieces of leather that compose the hose in length are connected by a double spiral joining of double rivets.

It is not, however, in this part that the greatest improvements have been introduced, but in the pump gear, in the air vessels, and in the whole structure of the Machine, which is now made with all the care and accuracy the important duty of the engine requires, and which only modern workmanship could supply.

It appears that the first double acting fire engine with an air chamber or air vessel, in England, was made by Mr. Newman, an engine maker in London, about the middle of the last century, and is therefore commonly known by the name of Newman's fire engine; although there seems to be no particular claim for its being thus distinguished, as we have seen the principle of this kind of engine was well known on the Continent before his time; it is probable, however, that he gave it its more modern and convenient form.

Modern fire
engine.
Pl. xxix.

(363.) A fire engine of this kind acting under a spring of compressed air is represented in plate xxix. This engine is now very differently formed by different makers, but the principle of action is nearly the same in all. **A B**, fig. 1, is a cistern about nine feet long and three broad, or in nearly these proportions. It is mounted on wheels, to which are attached shafts, whereby to draw it with horses, or a simple pole and cross handle, when only intended to be moved by men; the cistern is commonly made of strong oak planks, with the joints well secured by copper plates to prevent it from leaking. The hind axletree on which the two opposite hind wheels turn is a fixture to the bottom of the cistern; but the fore axletree, borne by the fore wheels, is put on a strong pin or bolt, fastened in the middle of the front of the bottom of the cistern, by which means the two fore wheels and the axletree have a circular motion, whereby the engine may be more conveniently turned round a corner, and be made to stand firm on a sloping plane. At the back part of the engine is a brass tubular projection with an external screw, and the companion screw is fixed to a long leathern pipe; this being attached to the part on the engine, the other end is carried to any river, pond, or ditch, from which water may be obtained, and thus furnishes a feeding or sucking pipe to the cistern; but when such source of water is not to be obtained, it is brought by hand in buckets, or rather according to the well-known process at fires, the buckets are handed along by a row of persons and emptied successively into the small trough at the end of the cistern seen in the figure at **G**; between which and the cistern is a fine copper grating to prevent any mud or dirt entering the latter, which would have an injurious effect upon the valves and pistons of the pumps. A similar trough is also placed at the front of the cistern, and furnished in the same way with a proper copper grating.

The pumps are worked by a number of persons seizing the long side rods seen in the figure, and frequently these are assisted by other persons standing on treadles inside the upper framing by their throwing their weight alternately from side to side, keeping themselves steady by means of two horizontal rails framed into four vertical stands which reach to the bottom of the cistern and are well secured to its sides. Over the hind trough there is an iron handle or key **K** serving to open or shut a cock placed under it on the bottom of the cistern. **L** is an inverted pyramidal box or case which preserves the pumps and air vessels from damage, and also supports a wooden frame or platform on which a man may stand to direct the current of projected water, either by raising or depressing it, or guiding it from side to side as occasion may require; the bottom part of the pipe being allowed this freedom of motion by being there formed of two pieces of brass pipe, each of which has an elbow. The lower end of this is screwed to a pipe which descends through the air vessel to the water, and to the upper part is screwed, by a well-fitted screw, the pipe or hose, so as to render it water tight in every position. The conical form of the directing pipe serves to contract the stream of water, and thereby to increase its velocity of projection; while the valves and leathern pipes of the engine have sufficient water way to supply the jet in its greatest velocity. Sometimes when the engine cannot be got sufficiently near to the place where the fire rages to have the water directed upon it from the pipe seen in the figure, a long flexible leathern hose may be screwed on in its place, and the pipe itself screwed to the other end; by this means the water may be carried inside the house on fire, or into narrow courts and alleys where the engine itself cannot be taken. Between the wooden case **L** and the fore end of the engine, there is a strong iron bar **O** lying in a horizontal position over the middle of the cistern, and playing in brasses supported by two wooden stands, one of which is placed before the fore stands of the upper rails, and the other within the box or case **L**. Upon proper squares of this bar are fitted, one near each end, two strong cross bars, and to these are fixed the two long cylindrical handles by means of which the engine is worked. The method of working the pumps is seen on an enlarged scale in fig. 2. **A B C D** is a double sector of iron, having sufficient breadth of sole to receive two chains resembling a clock chain; one end of one chain is fastened to the bottom of the arch head, and to the top of the piston rod, and the other chain is fixed at one end to the top of the arch head and the lower part of the piston rod, whereby, when the sector descends on one side, the chain fixed at its lower part winds round and pulls down the piston on that side, while in the opposite sector the chain fixed on the upper part of its arch head winds round and raises the other piston; the reverse takes place the next stroke, and thus a continual action is carried on, the pump acting by suction during the ascent of the piston, and by forcing during its descent. While either piston is ascending, the water rushes through the lower valve from the cistern and fills the cylinder, and when the piston descends this valve shuts by the pressure of the water, and is forced through the valve, seen in fig. 3, into the air vessel, the upper part of which is filled with air compressed by thus forcing the water in, and which thus acting by its elasticity on the surface of the water, causes it to be projected with velocities and to heights greater or less according to the degree to which the air

Machinery

Manufactures.

is compressed. The treadles for working the engine by men placed above the cistern are suspended from the hind arched heads above described, which work the pumps, and from a similar but smaller double sector, (having only to support the treadles,) seen at Q. The ends of the treadles at the hind part pass through openings in the piston rods, seen at H, G, fig. 2. The hind sectors are also seen in fig. 3, with the treadles passing through the opening as above described. This figure represents a section through the middle line of the hinder part of the engine, and also a section of the air vessel, and that of one of the barrels or cylinders, as likewise the elevation of the hind sectors and other parts. A B is the section of the bottom of the cistern, and C that of the hind axletree. D E is the vertical section of a strong piece of cast brass, iron or other hard metal, so worked as to have a hollow in it, and fixed to the bottom of the cistern. This reaches from the opening D to the cock W, and afterwards divides itself into two branches, so as to open under each barrel, but only one of these branches can be seen in the figure, the other being behind. Through this channel the water is conveyed to the pumps by the pressure of the atmosphere, either from the cistern itself or from any place at a distance, by means of the leathern feeding pipe which screws on to a projecting short tube D, under the hind trough Z, fig. 3, or under the trough G, fig. 1. F G, fig. 3, represents the vertical section of another piece of cast brass which may be called the communicating piece, having two hollows for conveying the water from under the two pistons to the two openings of the flanch of the air vessel, one only of which is seen in the figure; the other lies behind this, although not in a parallel direction. Between the section of the sucking piece D E, and that of the communicating piece F G, is seen the section of one of the plates of leather which makes all tight, and forms one of the two sucking valves, of which there is another just behind under the other barrel. R S T is the section of the copper air vessel, and I V that of the conducting pipe; this vessel is screwed on to the hind part of the communicating piece, and at the top is fastened by a collar of iron to a cross piece of timber. Between the flanch of the air vessel and the communicating piece is shown the section of one of the leather plates making all tight, and securing one of the two forcing valves, of which there is of course a similar one in the other opening not shown. These valves are loaded with a weight of iron or lead, having a tail let through the flap of the valve and cross pinner under it. It may be proper to observe, that from the nature of the operation when the water presses to open the valve in the air vessel, that which opens to the cistern is shut, and on the return stroke, when the lower valve is opened by the upward pressure of the water from the cistern, that in the air vessel is shut by the pressure of the air in the vessel, so that these valves can never be both open at the same time.

H I is a section of one of the pump barrels, which are both sucking and forcing, as appears from the position of the valves and the structure of the piston, each of which is composed of two iron plates, of two wooden plates, and of two flat pieces of leather, turned one up and the other down. L K represents one of the piston rods, seen edgewise, behind which is one of the chains, the upper screw of which, K, can only be seen. M is the end of the middle bar, and N a section of the hindmost of the two middle stands which support the middle bar,

and O represents the end of the profile of one of the treadles passing through the rectangular opening in the piston rod, as shown at H G in fig. 2. Machinery.

In fig. 3, X Y represents an iron handle by means of which the cock W may be set in any required direction; viz. either so as to make a communication between the cistern and barrels, or between the feeding pipe and barrels shutting off the cistern, according to the means by which the engine is supplied.

The principle of action is sufficiently obvious, the air being compressed in the air vessel by forcing in the water to (let us suppose) half its original bulk. The water will be pressed internally by the amount of two atmospheres, and outside with only one, consequently the internal pressure would sustain an external column of water thirty-three feet high; and to this height the water will be projected, except some small diminution arising from the friction of the water along the pipe and the resistance of the atmosphere. If the air be further compressed by an additional quantity of water to one-half its last bulk, or to one-third its original bulk, there will be the pressure of three atmospheres internally to one externally, and the internal pressure would support a column sixty-six feet high, to which height the water may now be thrown, and so on for greater or less pressures; a force, however, internally of three atmospheres is generally amply sufficient for most cases. The engine above described is one of the most simple of the kind. It has been stated that they are now made of various sizes and forms, and some with double force pumps; the general principle, however, is the same, and the above description will be therefore sufficient.

(364.) *Local fire engines.*—The fire engine above described may be distinguished as a locomotive engine, readily removed from place to place, either by the aid of men or horses; but of late years it is not unusual in large establishments to have local engines which are immovable from the situation in which they are placed. In the Royal Arsenal at Woolwich a substitute for an engine of this description is furnished by a permanent reservoir about seventy-eight feet above the arsenal. The pressure of the water from this natural head supplies, of course, a power equivalent to such a column, and in case of any accident in which its aid is required, the simple turning of a cock supplies at once not only the water, but a pressure sufficient to carry the stream over the highest buildings; an object of great importance in an establishment where so many valuable stores are deposited, and where so many combustible and explosive materials are deposited. Local fire engine.

In his Majesty's Dock-yard at Chatham, this object is attained by the construction of a powerful forcing engine placed under the level of the yard, and which is worked by eighty men at capstan bars; the vertical shaft connected with the head of the capstan is supported on a proper bearing about six feet below the ground surface, and a little above its bearing is furnished with a large horizontal bevelled wheel which acts upon a smaller bevelled wheel placed vertically on a strong horizontal shaft, supported by proper bearings, and having three cranks upon it placed at angles of 120° with each other. These cranks work pump rods which descend to three pump barrels of eight inches bore, and which force on the ascending stroke. All these barrels communicate with one large and strong cast iron air vessel in which the air is kept in a high state of compression, and forces the water along a main pipe, which may be opened by

Manufac-
tures.

proper plugs at almost any part of this great establishment where its service is at all likely to be required.

The late Sir William Congreve also was the projector of local fire engines of a different kind, but we believe they have been but little adopted. His plan consisted in placing a large reservoir of water on the top of any building of great magnitude or importance, such as Government or Mercantile storehouses, warehouses, &c., as also Playhouses, and places of public amusement; from this reservoir descended pipes to those parts of the building where accidents were most likely to occur, or which it might be considered of the greatest importance to protect, so that the moment an accident occurred the means were at hand to check the progress of the flames; and indulging his imagination, some of these pipes were furnished with adjutages which revolved with the force of the water issuing from them, and thus cast it about the building in all directions. A model of a design of this kind, intended for Drury Lane theatre, was for several years exhibited in the Repository at Woolwich, the action and operation of which displayed great ingenuity.

The importance of the fire engine in every town cannot but be fully admitted; but of all towns or cities, the metropolis of this Country, the most populous in Europe, stands more in need of this Machine than any other, and is accordingly much better provided with them, many of them of the most powerful description; their places of deposit are well known, and premiums are paid to the earliest engines that arrive. Another convenience is provided in London, and in most large towns artificially supplied with water, *i. e.* proper water plugs, which may be generally opened on the spot, to furnish the requisite supply of water for the use of the engine; and various ingenious contrivances have been employed to add to these, a Machine of general application, called a Fire-escape, for saving the lives of persons and valuable property from the upper part of a house which is already so much enveloped in flames as to prevent any interior communication.

Various Machines of this kind have been proposed, of which several are described in the *Transactions of the Society of Arts*, and from which we select the one given below. This is taken from vol. xxviii.; others may be seen by consulting vols. xxxi., xxxiv., and xxxix.

Fire-escape. (365.) *Fire-escape by Mr. Davies.*—This is meant to be a Parish Machine, kept, as the fire engine is, always in repair, and always ready to be applied on the first alarm. It consists of three ladders applied to each other by four clasp irons on the top of each of the two lowermost, which are so contrived that each ladder may slide into the one beneath it; on the top of the lowermost ladder two pulleys are fixed on the inside, over which two ropes pass, and are situated between the lower ladder and the middle one. The ropes are made fast to the bottom of the middle one on each side in a proper direction with the pulleys on the top. The upper ladder is attached to the middle one in the same manner, and on the top it carries two horn pieces made of iron, and turned off at each end similar to two horns, which are four feet wide; their ends are sharp, to pitch on each side of a window, and with its points hold the ladder steady. The three ladders when shut down are fifteen feet in height. They are placed perpendicular in the middle of a framed carriage of nine feet six inches long, and five feet six inches wide, mounted upon four wheels. On each side of the carriage a windlass is placed, to which ropes are attached,

and also to the bottom ladders; these are passed over pulleys, so that by turning this windlass the ladders may be wound out from their standing height of fifteen feet to forty-five. Over this windlass is a screw turned by a winch, by turning which the ladders may be inclined against the house with all imaginable ease. On the top of the upper ladder, on the outside, are two pulleys, over which two chains are conducted to the windlass on one side for the purpose of carrying up a box, two of which travel with the fire-escape; so that in the event of one being filled with small valuables it may be unhooked, and the other put on, which will save time. The whole apparatus may be drawn by one horse or six men, and when arrived at the scene of danger, may be adjusted in a few minutes. *Society of Arts*, vol. xxviii.

(366.) *Garden engine.*—This is very similar in its construction to the old fire engine, but is of course on a much smaller scale, is made generally to be worked by a single handle, and is seldom supplied with an air vessel. The larger sort is mounted on wheels which are attached to the cistern, others are supported by a single wheel and two front feet like a wheelbarrow; others again are detached from the cistern, being in fact little more than a portable forcing pump, intended to be worked in buckets of water. These kind of engines, however, are too common and of too trivial a character to require further description in this place.

(367.) *Pile engine* is a term usually applied to a simple but very useful Machine employed a great deal in Hydraulic Architecture, and frequently also in other cases; but in the construction of bridges, wharfs, docks, basins, &c., it is indispensable, and some ingenuity has been exercised in giving it the most convenient form. The object of this engine is the driving of piles for forming the sides of quay walls, and for carrying the sleepers for the foundation of heavy buildings of all kinds where the soil itself has not sufficient solidity to afford a proper resistance to the weight of the erection.

Without attempting a description of the Pile engines commonly given in our Works on Mechanics, which are now very rarely if ever employed, it is proposed to explain one of the most simple kind as it is now commonly made. This (represented in plate xxix.) consists first of a base formed by four timbers crossing each other at right angles, and bolted together, and to the two cross timbers is bolted a crab, with a barrel and two handles (not shown.) This is worked by four or more men. Between the cross timbers at A and B, fig. 5, are erected two upright pieces of timber defended by thin plates of iron, on the other side is a ladder sloping towards the top for the convenience of ascending, and the whole is then securely braced in an erect position by the side props seen in fig. 5 and 6; a wheel or large pulley is fixed at top, over which a rope or chain passes; one end of this is fixed to the barrel of the crab, and the other to a part called the monkey: this piece is shown in fig. 7. The monkey has a front and back plate, the latter of which, being removed, allows the other part to pass between the upright slides; the back plate is then screwed on and the nuts so adjusted as to enable the monkey to slide freely up and down the slides of the Machine. The rope is attached at H, and below, as at G, the nippers shown in fig. 8 are suspended from their axes. These take hold of the handle or ear on the ram W, fig. 9, the weight of which, as well as their form, preserve them shut, and the ram having a back plate the same as the monkey, is prevented from rebounding

Machinery.

Garden engine.

Pile engine. Pl. xxix.

Manufactures.

away when it falls. The method of relieving the ram so as to give it a free descent, is as follows:—On the upper part of the slides, fig. 5, are seen two inclined planes K L; and it will readily be perceived that when the monkey has been raised so high that the bowed handles of fig. 8 enter between them, these will be compressed by the same force that raises the weight, and by their closing, the bottom part of the nippers will open and the ear of the ram will escape between the lower jaws, and fall with its entire momentum upon the top of the pile. The weight of the ram is commonly ten hundred weight. This being now below, the weight of the monkey and nippers together is sufficient to cause these to descend by their own gravity; they thus come again in contact with the ear of the ram, and their shape is such that they will open by the pressure and admit this ear as before, and close again so as to be ready to be once more lifted by the effort of the men at the crab. When arrived at the top, the inclined plane closes the handle of the nippers as before, and the ram again falls; the operation being thus repeated till the pile has been driven the proposed depth into the soil, which is sometimes a work of great time and of considerable labour. In order to defend the pile from splitting by the blows at top, it is encircled by a stout iron hoop, driven on to its upper part, while to facilitate its penetration, it is furnished at bottom with what is called an iron shoe, which is pointed, and gradually expands to the size of the pile, the latter being itself tapered by an adze.

Withdrawing piles.

The pile being driven, is sometimes to remain in its place, and frequently it is requisite to cut off the upper parts of a row of such piling under water to a straight line; (this is done by a Machine described under the article Saw-mill;) at others it is necessary, after the work for which the piles were driven is completed, to withdraw them again. This generally occurs in building stone or brick walls for quays; the piles being employed only to form a dam against the water during the erection of the wall. This operation is commonly effected in tide rivers and harbours by attaching barges to the pile at low water, and then, as the tide rises, the barge rises, and the pile must follow or pull the barge under water. Should the latter be probable, the barge must be made free, and a vessel of greater floating power employed. Bramah's hydrostatic press also has been sometimes employed for this purpose.

Questions respecting the proper height of pile engines.

(368.) The height to which the ram of a pile should be raised to produce the best effect, as regards the ultimate time of driving, is a question which can hardly ever become of practical importance, because the engineer is frequently limited in his means by other considerations than those of employing the least time; although, as a matter of economy, the latter point must not be wholly overlooked. The subject, however, some years ago, engaged the attention of several able scientific men. It is obvious that the higher the ram is lifted the longer time will be employed, not only in the operation of lifting, but also in the time of falling; but the blow will be greater also, and that in a higher ratio than the time; because the velocity is as the square root of the height, whereas the time is as the height merely: hence arose a question of maxima and minima, which led to great controversy; some making it appear that the effect would be greater the greater height, and others that it would be greater as the height was less. The parties engaged in this controversy were of some considerable scientific eminence; and it is rather to show

the fallacy of depending wholly on theory in practical cases, than for any other purpose, that we give the following remarks on this controversy, from the fourth volume of *The Collection of the Mathematical Papers from the Ladies' Diary*. Machinery.

It is easy to conceive that a pile may be driven so far into the ground that no power which it is possible to apply in the usual way can have an effect in producing any further motion in it. We are not, however, left to mere supposition and conjecture on this head, as this circumstance really occurred in driving the piles for the bridge of some mills, where the soil upon which the bridge was to be erected was pure sand of uniform density to the depth of 47 feet, yet no piles could be driven lower than 15 feet, although the rammers in the engines employed were enormously large.—Gregory's *Mechanics*, vol. i. p. 292. Hence it appears that it is possible to drive a pile so far that all future operations of the ram become wholly useless; yet there can be no doubt that if a sufficient momentum were applied, motion might be produced. Hence it follows, that whatever may have been said with regard to the incongruity of percussion and pressure, there is in reality a momentum which is precisely equivalent to the pressure and resistance of the pile; for since, as in the case we have mentioned, a momentum may be too small to produce any motion, while with a greater momentum motion will ensue, it follows that somewhere between the two a momentum may be found which is just sufficient to produce an equilibrium between itself and the resistance and pressure of the pile.

This circumstance, it is obvious, must always have place in all operations of this kind; that is, after the pile has been driven to a little depth the resistance will be such as to require a certain momentum to produce an equilibrium in the pile, and any momentum less than this will have no effect, however often repeated, in producing the required motion; and therefore if any greater momentum be applied, it is obviously only the difference between this, and that which is expended in putting the pile in equilibrium, that becomes effective, and which ought alone to be considered in computing the effect of the engine; and it is, doubtless, for want of duly attending to this circumstance that so many erroneous solutions have been given to this question. As to the momentum that may be necessary for producing the required equilibrium, it is obvious, from the various circumstances which may arise in the application of the pile engine, that this can only be determined by experiment, on some principle similar to the following. Suppose by experiment it is found that a momentum m drives the pile a inches; and a momentum M drives it b inches; and let it be required, hence, to determine the momentum y , which is equal to the resistance of the pile.

The first effective momentum is $m - y$, and the second $M - y$; and now admitting each effect proportional to its cause, we have $m - y : M - y :: a : b$, whence $b m - b y = a M - a y$, or $(a - b) y = a M - b m$, or $y = \frac{a M - b m}{a - b}$; which is the momentum equal to the resistance of the pile. Find the height due to this momentum, and call it h , then the solution of the problem will stand as follows:

Let x be the required height to produce the maximum,
 a the velocity per second in drawing up

2 q

Manufac-
tures.

t the time in falling,
 h the height necessary to produce the equilibrium,
 $g = 16 \frac{1}{2}$ feet,
 w the weight of the ram.

Then supposing the momentum to vary as the velocity, we have $2gt = v$; $vw = m$, the generated momentum,

$$\frac{x}{a} = \text{time in drawing up,}$$

$$\frac{\sqrt{x}}{\sqrt{g}} = \text{time in falling} = t,$$

$$\frac{x\sqrt{g} + a\sqrt{x}}{a\sqrt{g}} = \text{the whole time,}$$

$$2\sqrt{gx} = v, \text{ or } 2w\sqrt{gx} = m,$$

$$(\text{by substituting } \frac{\sqrt{x}}{\sqrt{g}} \text{ instead of } t.)$$

And h being the height due to the momentum above determined, this will be expressed by $2w\sqrt{gh}$, and consequently $2w\sqrt{gx} - 2w\sqrt{gh} = 2w(\sqrt{gx} - \sqrt{gh})$ is the effective momentum, which, divided by the time necessary for the production of it, must be a maximum; that is,

$$2w \frac{(\sqrt{gx} - \sqrt{gh})}{x\sqrt{g} + a\sqrt{x}} = \text{a max.,}$$

or

$$\frac{\sqrt{x} - \sqrt{h}}{x\sqrt{g} + a\sqrt{x}} = \text{a max.}$$

This, thrown into fluxions, gives

$$x \left\{ \frac{1}{2x} (x\sqrt{g} + a\sqrt{x}) - \sqrt{gx} + \sqrt{gh} \frac{x}{2\sqrt{x}} (\sqrt{x} - \sqrt{h}) \right\} = 0,$$

which reduced, gives

$$\frac{1}{2}\sqrt{gx} = \frac{1}{2}a\sqrt{\frac{h}{x}}\sqrt{gh},$$

or

$$x\sqrt{g} = a\sqrt{h} + 2\sqrt{gh}x,$$

or

$$x - 2\sqrt{hx} = a\sqrt{\frac{h}{g}};$$

whence

$$\sqrt{x} = \sqrt{h} \pm \sqrt{\left(h + a\sqrt{\frac{h}{g}}\right)},$$

or

$$x = \left\{ \sqrt{h} \pm \sqrt{\left(h + a\sqrt{\frac{h}{g}}\right)} \right\}^2,$$

the height required.

In the above solution has only been determined the height, when any single momentum, divided by the time necessary for the production of it, is a maximum; whereas the problem requires that the sum of all the momenta, divided by the whole time, should be a maximum. In order to determine this, we must assume a certain law of resistance, to which, applying the above principle of solution, a general result will be obtained. But as this assumed law of resistance must be totally supposititious, and probably very different from that which arises in practice, the preceding determination (supposing the value of h to have been found by experiment towards the conclusion of the operation of the engine) is probably more accurate than that which would result from the above supposition of a variable law of resistance. For it must be observed that x , as found above, is always the same function of h , that h increases as the blows are repeated, and consequently x also increases

each blow; but the distance between the top of the pile and the top of the engine also practically increases each stroke by the depth the pile has penetrated. It is therefore probable that the value of x found as above for any single stroke is very nearly, if not accurately, that which answers for the whole sum. We have already stated that this solution is not given so much with a view to real utility as with that of pointing out the necessity of attending to all the practical bearings of a question before we can hope to derive any assistance from theoretical investigations.

(369.) *Iron piling.*—Till very recently piles were always formed of timber, armed, as has been stated, at bottom by an iron shoe, and at top by a stout hoop or ring of iron; but, lately, Mr. R. Sibley, architect, of Great Ormond Street, suggested the piling with iron, and presented his plans for carrying these views into practice to the Institution of Civil Engineers, in which they led to considerable discussion, and excited, by the novelty of the idea, great attention. The first work of this kind was constructed, under the direction of Mr. Sibley, at the Island Lead Works, at Limehouse; a second work has since been executed by him, in forming a wharf at the South foot of the new London bridge; and another is now in progress on the opposite side.

In the wharf already constructed the piles are each in one casting, thirty feet long, and hollow throughout, chisel-pointed at the end, to facilitate their penetration into the soil, and in case there should be any stoppage to endanger the pile, or to cause it to take a wrong direction, a borer or jumper is used through the hollow of the pile. The piles are of a somewhat elliptical figure, with two pretty deep grooves one on each side. They are driven to their proper depth at distances of ten feet, and then iron plates of the same length, ten feet, are slipped down in these grooves, and form the facing of the wharf. Mr. Sibley, in a letter to the writer of this Essay, says, "The most eligible method to pursue in constructing a wharf on this principle is first to dredge the bed of the river to the intended depth, then to pitch and drive the piles, removing any impediment by the auger, or by jumping through the hollow of the pile, then to secure the piles by iron ties, fill in the plates, and back in the concrete."

The expense attending this method of forming a wharf is very inconsiderable when compared with that of erecting a stone face: the whole cost but little exceeding that of the coffer-dam necessary to be first constructed in such cases. The wharf at present constructing on this plan, at the North foot of London bridge, will be twelve feet above low-water mark.

Since this first suggestion by Mr. Sibley some deviation has been introduced into the practice by Mr. James Walker: an iron faced pier being now in course of construction at Blackwall, under the superintendence of Mr. George Bidder. In this the whole face of the pier is formed of piles, viz. main piles at every ten feet, and the intervals filled up with iron sheet piling, every other one overlapping two others, and supported at the top by one connecting piece, and by shoulders cast on the main piles. In this construction the question whether cast iron piles can be driven in hard soil has been put to a severe trial, a hard substance, known by the name of the Blackwall rock, lying a little below the bed of the river, having been penetrated, with but few accidents to the pile. In this work, however, the

Machinery

Iron piling.

**Manufac-
tures.** main piles are not all in one length, as in that above described, but formed in two, the hollow in the bottom part receiving a projecting end on the upper. The ram used in driving the piles weighs fifteen hundred weight, but its immediate blow on the head of the pile is intercepted by a piece of timber placed on the pile, which considerably relieves the jar, which would be most likely to injure the iron. We shall recur again to this subject in speaking of the construction of wharf walls, &c.

Miscellaneous Machines.

(370.) *Machine* is a very comprehensive term in practical Mechanics; we have seen that some Machines are denominated engines, others mills, &c. Those which retain the general denomination of Machines are also sometimes particularized by the nature of the processes in which they are employed; as Block-making Machines, Planing Machines, Blowing Machines, while others are designated according to their forms or objects, as cranes, jacks, locks, presses, &c. It is proposed in this section to give a description of the most general of these, arranged according to their alphabetical order; others which have only a particular application will be best described under the mechanical process or Manufacture in which they are exclusively employed.

**Block Ma-
chine.** *Block-making Machine.*—This denomination has been given to a very ingenious construction, consisting of numerous separate Machines worked by a steam engine in His Majesty's Dock-yard at Portsmouth, and of which a duplicate is also in store in Chatham Dock-yard. Before the year 1807, all blocks, as well for the Royal as for the Mercantile Navy, were formed by hand, although at that time different descriptions of saws were used, worked by Machinery, for the purpose of cutting and converting the timber into the sizes for the blocks; but the rest remained to be effected by hand; such as giving to the blocks their proper form, mortising, rivetting, &c. In the works we are about to describe, all these operations are performed by different Machines, constructed each for its individual purpose, and the whole in combination is, perhaps, one of the most interesting mechanical performances that can be well imagined.

The Machine, as it at present exists, is due to the inventive genius of Mr. M. J. Brunel, who has displayed as much judgment in the division of the operations by the several Machines, as ingenuity in the contrivance of their parts, which are admirably calculated to produce their intended effects. The greatest attention has been every where paid to that form of construction which would admit of the most perfect workmanship in the execution; and in this the ideas of the inventor were ably seconded by the late ingenious Mr. Henry Maudslay, who made the Machines with the most scrupulous attention to accuracy and durability, at the same time preserving that elegant proportion in their form for which the works of this engineer have always been so much distinguished.

Blocks are formed of elm, and the timbers are received at this mill in their rough state. These are first cut into short lengths proper to form the various blocks, by two large saws, one reciprocating and the other circular. The timber being thus reduced to planks of a proper thickness, is next cut into squares and ripped or split up into the proper sizes by four sawing benches with circular saws; there is also one very large reciprocating saw which is used for cutting up the pieces for

the larger blocks. The pieces being thus prepared are perforated by the three boring Machines, with a hole through each to contain the centre pin for the sheaves of the block, and as many other holes in a perpendicular direction to the former, as the number of sheaves it is to have, these holes being intended as the commencement of the several mortises to contain the sheaves.

The blocks are now mortised in three mortising engines, which elongate the holes above mentioned to their proper dimensions. The corners of the blocks are next cut off by three circular saws, preparatory to reducing them to the elliptical figure they are to have. The next process is to give them their outside figure by means of what are called shaping Machines, of which there are also the same number, three, each of which forms every part of ten blocks together. The scores or grooves are next formed round the block to receive the rope or strap by which they are to be suspended; this is done by two scoring Machines. The blocks now undergo the only manual operation to which they are submitted to smooth and polish them.

The block being thus far advanced, the next business is forming the sheaves. The first process here is cutting pieces of a proper thickness from the ends of trees of *lignum vitæ*. This is performed by what is called a converting Machine, of which there are also three; one consisting of a reciprocating saw, and the other two circular saws. These thicknesses, which already approximate towards the circular form, are cut circular and bored centrally at the same time by what are denominated trepanning or crown saws. A hole is now made in the centre of each sheave for receiving the coak or piece of bell metal which is fitted into the centre of each sheave to form a socket for the centre pin, and these being put in their places are rivetted fast by two rivetting hammers.

In some cases three small holes are drilled through each sheave and also passing through the coak, by the drilling Machine, and short wire pins, cut by the cutting shears, are put through these holes, and they are then rivetted down at the same time with the coak, by the rivetting hammer; but this is not always done, as the coaks are found to be firm enough without these pins or rivets.

The centre holes through the coaks are next broached out to a true cylinder in the three *broaching engines*. The last process is turning the faces and edges of the sheaves to a flat or rather to a slightly convex surface, in the three *facing lathes*, which also form the groove round the edges of them for the rope which encompasses them when in the block. This completes the Machines for making the sheaves. The iron pins are forged by two smiths in the usual manner of such articles, between two swages or tools, each having a semicylindrical cavity formed in it, so that the two when put together, form a cylinder. The heated iron being laid in one of these, the other is put over it, and beat with a hammer, by which means it forms the pin to a cylinder. The end of the pin is left square for a very short length. They are in this state turned smooth and true in the *pin turning lathe*, and afterwards polished and made perfect on the surface in the *polishing Machine*.

Such blocks as are from four to seven inches in length, are generally fitted with wooden pins, which are turned in a simple lathe. There are also two Machines for making *dead eyes*, and a large apparatus or boring

Manufac-
tures.

Machine for making the largest sizes of blocks, of that denomination called *made blocks*, some of which are as much as four feet in length, and with four sheaves. They are of course made up of planks, and this Machine is used for boring the holes of the numerous bolts which are used to unite these parts; it is also used for purposes unconnected with block making.

The number of Machines employed in these works is forty-three; the reader will therefore see that notwithstanding the great ingenuity displayed in them, it would be impossible for us to attempt a graphical illustration; nor is it indeed requisite that we should do so, because many of them, although possessing certain peculiarities to accommodate them to the purposes for which they are intended, do not differ essentially from other engines and Machinery described under their respective denominations in this Treatise. We shall endeavour, therefore, to give a verbal description sufficient for comprehending the general nature of the process as it relates to the application of Machines described in other parts of this Work, and shall attempt a graphic delineation of only one or two of those which are exclusively employed in the process of block making.

Different
kinds of
saws.

(371.) The saws, as we have seen, are of different kinds. One large reciprocating saw for cutting up the elm into planks of different thicknesses; for a description of which we may refer to the article Saw-mill, where also is described and delineated the revolving circular saw for cutting the *lignum vitæ* into flakes of the proper breadth or thickness for forming the sheaves. Besides these, there are several sawing benches with circular saws, which do not differ essentially from those described under the same article. The great reciprocating cross cutting saw may be readily comprehended. The tree subjected to the action of this Machine is placed on a long frame or bench raised a little from the floor, and at the end of it is erected a frame; through this the end of the tree is drawn by a capstan, its end projecting as much from the surface of the frame as is intended to be cut off; it is fastened in the frame, to prevent it rolling sideways, by a lever which can be easily made to press upon it and hold it down. The saw itself is a straight blade, fixed into a wooden handle or pole at each end. One of these handles is connected by a joint to the upper end of a lever bent like the letter L, and having its centre beneath the floor; the horizontal arm of the lever with a spear rod is worked with a crank on the end of a spindle near the ceiling, the motion of which is regulated by a fly wheel; this gives to the saw a reciprocating motion from right to left nearly in a horizontal position, and exactly across the log it is intended to cut off. In the commencement of its action the saw is guided in its vertical position by its back entering a saw kerf fixed in the frame, but as the operation of sawing proceeds the saw quits this saw kerf and is then guided by the cut already formed in the timber. The saw works by its own weight, but it may be lifted up at any time from its work by means of the handle which the attendant lifts and suspends by a rope when necessary; the saw will then continue its reciprocating action without cutting, being thus raised above its work.

Boring
Machine.

(372.) It has been already stated that after the elm is cut into the proper scantling, it is reduced to blocks of a proper size, square or rectangular, and that the next process is the boring. The boring Machine is a sort of compound lathe, having its mandrels placed at right angles to each other, to bore the blocks in these opposite

directions. These mandrels carry the boring tools which are pressed against the block secured in an iron frame which keeps it perfectly fixed and steady: on one side a central hole is bored for carrying the pin on which the sheaves are to turn, and on the other as many holes are formed as there are to be sheaves, each forming the commencement of the mortises in these directions, as already explained. This Machine is very ingeniously contrived, but it does not differ so far from what may be easily effected by a common lathe as to require a graphic delineation. The greatest difference is, that in common practice the block would be turned at right angles, elevated or depressed, and the holes bored by the same mandrel; whereas here two mandrels being used, placed exactly at right angles to each other, and at the requisite heights, the whole process is carried through with the block remaining in its first well-secured position, which is of course much better where the work to be performed is, as in this case, sufficient to answer the purpose of erecting a Machine exclusively for this purpose.

(373.) The next process is the mortising, and the Machine used in this process is one which belongs exclusively to block making, and requires therefore a more minute description. A plan of this Machine is shown fig. 1, pl. xxx. where *x x* represent two blocks secured in their places by the screws *r r r*, only two of which are shown as acting in the figure; *C D* is a carriage of iron sliding on a proper bearing or bed in the main frame, the advancing movement being communicated to it by means of a screw *L*, fitted through a nut in the centre of the ratchet wheel *M*, which turns round a socket formed to a cross bar *N* of the framing: thus, when the wheel is turned round, it operates upon the screw to advance it with the carriage and block at the same time; the ratchet wheel is turned round at intervals by means of a tooth formed in a rod, nearly the same as the timber is made to advance in a reciprocating saw-mill, the block moving forwards by this means the thickness of the chip it is intended the chisels are to cut at each stroke. The chisels are fixed in a vertical frame and rendered very secure in their places, the vertical frame itself being made to ascend and descend with immense velocity; and there being as many chisels as there are mortises to be formed in all the blocks in the frame, the whole process is performed in a very short time, the chisels moving with such velocity that it is absolutely impossible for the eye to follow them; and to a stranger looking on, the formation of the mortises appears like a work of magic. The ratchet wheel *M* has a cog wheel *P* fixed to it, which has its teeth engaged in a smaller wheel below, (not seen in the figure,) fixed on a long spindle extending to the front of the Machine, which has a handle fixed to it, and by means of which the workman can at any time bring the carriage to the proper point for the commencement of the mortise, and by this means the action of the screw is at any time cast off.

The chisels are provided with small teeth which are fitted into dove-tailed notches formed in the blade of the chisel: these are called scribes. They have a sharp edge projecting a small distance beyond the inside edge of the chisel, and therefore in descending through the mortise, the scribes cut the sides of the mortise clear, and cut at the same time two clefts, which separates the chip, which is to be cut out by the next stroke, at its edges from the inside of the mortise, so that the chip comes out clear without splitting at the edges; thus

Mortising
Machine.
Pl. xxx.
Fig. 1.

Manufactures.

making the inside of the mortise as clean and smooth as possible. Each chisel has also a piece of steel fixed on before the edge, by a screw which projects from the middle of it, and is screwed into its blade, the upper end of the piece being received in a notch or groove formed in the chisel. This piece is for clearing the chips out of the mortise as fast as they are cut; for though in general these fall down through the block, yet it may happen they will stick in, in which case without this precaution they would clog up the mortise with chips so as to impede the proper action of the chisel.

It should have been observed that the screws which secure the blocks in the boring Machines, make a certain central impression and a ring on their ends, and that this centre is the guide for fixing the blocks fast in the mortising Machine, the points on the screws *r, r, r* being carefully introduced into the centre previously made, and the rings of these are also of precisely the same size as those on the screws of the former Machine, and by this means the utmost accuracy of position is attained. We do not attempt to give a graphical illustration of the Machinery by which the motion of the chisels is obtained. The reader will easily conceive a strong vertical iron frame standing over the place where the blocks are represented in the figure with an interior frame carrying the chisels moving up and down in well-secured slides with great velocity, the motion being communicated to the moving frame by Machinery connected with the shaft of the steam engine, and that as the motion proceeds, the sliding frame carrying the blocks is gradually carried forward by the means already described, each advance of the blocks answering to each descending stroke of the chisels, and amounting each time to the thickness of the intended chip.

Corner cutting Machine.

This process being completed, it has been stated that the next consists in cutting off the corners of the blocks so as to approximate them towards the elliptical-shaped figure they are ultimately to have. This process being simply the work of another circular saw, requires no separate description. It will be sufficient to observe that in this, as in every other operation, the fixing and placing the block is so arranged that the most exact performance is insured.

Shaping Machine. Fig. 2.

(374.) The succeeding operation is that of shaping; and here again a Machine is employed exclusively applicable to this purpose, and it is one in which the ingenuity of the inventor displays itself in the strongest light. This consists of a double wheel in which ten blocks are fixed at once. The wheels are then put in rotation, and a gouge is so placed as to intercept them and form their external surfaces to segments of the circle in which they revolve. The plan of this Machine is represented in fig. 2, where *A B* are the two wheels fitted on a common axis, and which together form what is called a chuck. Two of the blocks are represented at *E E*; the figure shows the manner in which they are fixed in their position by the screw *a*, which has a steel ring fitted upon the point of it, exactly the same in all respects as the ring on the point of the screw *r* in the last figure. This ring of the screw *a* being inserted into the impression made in the end of the block while in the boring and mortising Machine secures one end. The other is retained by a ring *b*, of the same dimensions, containing two others within it, which enters the impression made in the other end of the block by corresponding sized rings in the mortising Machine. The

Machinery

double ring *b* is formed in the end of a short spindle, fitted in a socket through the rim of the great wheel *A*, exactly opposite the screw *a*, and has on the outside of the wheel a small toothed wheel *d*. The screw *a* being tightened up by a winch, the block becomes fastened in between the point of it and the spindle *b*, as if it were in a lathe. The compound wheels *A A, B B*, or as it is called the chuck, being thus fitted with blocks, has a rapid circular motion given to it by means of an endless rope encompassing the pulley *F* on the main axis. It is evident that a cutting tool being now presented to the blocks as they revolve, will form their exterior surfaces to segments of circles of the diameter of that in which they revolve. This tool, which is a gouge, is held in a sliding rest; this consists of a dove-tailed slide *G* accurately fitted into a groove *H*, which is attached to a long metal bar *I*, curved to a segment of a circle at one end; this is fitted on a centre piece fixed in a cross bar of the frame exactly beneath the centre of the axis of the chuck. The other end of this bar, which may be called the radius, rests upon a part of the framing *L* which is curved to a circular size, and on this the radius rests as it sweeps on its centre from one side to another of the Machine. The slider *G* for the gouge is advanced to its work by a lever having a handle *m* at one end, the other being fitted on a centre pin *n* fixed in a projecting part of the frame *H*; to the middle of the lever a short connecting bar *h* is jointed, and communicates the power of the lever to the slider *G*, and consequently advances the gouge *g*, which is held in the end of it, towards its work; but the quantity of this advance is determined by a roller, the axis of which is fitted in a socket attached to the slider *G*; it bears against a guide or pattern ruler *N*, which is supported on two pillars from the frame of the Machine. This pattern ruler has such a degree of curvature as the block is intended to have in this direction. This being understood, and the chuck supplied with the ten blocks as above described, the slide rest is moved quite to the end of its slider *L*, and in this state the Machine is put in action. The workman now holds the handle *m* in one hand, and the long handle *R*, which is attached by a joint to the frame *H*, in the other hand; with the former he presses towards the Machine to keep the roller above mentioned in contact with the ruler *N*, and with the other he sweeps the gouge slowly and steadily from one side of the frame to the other. In this circuit the gouge removes the angles of all the ten blocks at once, reducing them on the outside to the shape shown in the figure. This being done, the Machine is stopped, and it is necessary to turn all the blocks round one quarter on their respective axes to present another side outwards that it may in its turn also be brought to its proper figure. This is accomplished in a very ingenious manner, indeed, more ingenuity appears to be employed than the object attained justifies the adoption of. Each of the small spindles *b* has a small wheel *d* fixed upon it, and to each of these an endless screw is adapted. The axis of these screws *f* tends to the centre of the chuck, and each has a small bevelled cog wheel upon it. All these are turned by one large bevelled wheel *O*, which is fitted upon the main axis, but slips round freely upon it when this is in action. This wheel has a pin projecting from a part of its circumference which is detained by means of a stop jointed to the frame at the lower end and forked at top to catch this pin, when it is moved on its joint so as to approach the wheel, but

Manufactures.

when thrown back by a spring in its joint, it is out of action. When the blocks are to be turned round one quarter, this stop is pressed towards the wheel, and the pin, by turning the chuck round, catches on its fork, and prevents the wheel from turning. The workman now turns the chuck round four times, and in these four revolutions of the chuck, the centre wheel remaining stationary, the blocks are by means of their respective endless screws turned round one-fourth of a circle, and the corresponding face of each block is turned outwards to be subjected to the action of the gouge in the manner already described; but the sides now exposed to its action being those in which the mortises are formed, are of a more rapid curvature by employing a different pattern ruler. These sides being faced, the blocks are again turned another quarter round, and then again, when the figure is completed on all sides.

Scoring Machine.

(375.) The next process, and which is also the last, is that of scoring the blocks; this is performed by the scoring Machine, which excavates a groove on the block for the reception of the strap or rope by which it is suspended when in use. This is deep enough at the ends of the block to receive one half the thickness of the rope or strap, but is reduced to nothing where it crosses the pin of the block. This operation is effected by a circular brass wheel, which, in two opposite sides of its circumference, has openings in which are fixed two cutters with round edges projecting a little beyond the rim in the manner of a plane iron, and act as such. These brass wheels (there being two belonging to each Machine) are fixed over the centre of each block that is to be scored, the blocks being first secured in their places by means similar to those explained in speaking of the Machines already described. The frame which carries the blocks turns on an axle, so that they may be inclined to meet the cutter and thus admit of the score being made deep towards the extremities, while it is scarcely seen in the centre. The cutters also are on spindles which turn in a frame movable on a joint at the back of the frame of the Machine; and by means of these two adjustable parts, and a pattern to limit the curvature and depth of the score, this last process is effected and the block is completed, except a slight dressing by hand to remove any trifling roughness which may appear in the mortises when the tools are not in the most perfect order.

Trepanning or crown saw.

(376.) It remains to say a few words on the formation of the sheave. The trees of lignum vitæ being cut in flakes of proper thickness by the converting saw, these are now subjected to the action of the trepanning or crown saw: this may be described as a cylinder of steel having teeth cut upon its end; it is fitted on what may be considered as the mandrel of a lathe, but so as to slide freely upon it with the pulley by which it receives its motion. Within this cylinder is another axis and pulley revolving the axis carrying the borer to form the centre hole of the sheave. The sheave itself is held fast in its position by a screw, in what may be called the back centre of the lathe, and the saw and borer are made to advance upon it by means of a lever or handle urged forward by the workman. Thus the true circular figure is given to the sheave, and at the same time the hole for receiving the coak is also formed and rendered truly central with the circumference; at the same time impressions are made on its surfaces by the rings fixed to the ends of the screws, and the support between which it is held, which impressions serve as guides in fixing it again central in

any future process it has to undergo, such as broaching the coak, &c. Machinery.

The sheave being thus far formed, the next operation is to complete it for the reception of the coak. To comprehend this, it will be proper to describe the form of the coak itself. This consists of a part called the barrel, which just fits the circular hole in the centre above described, at one end of which is a flanch about double the diameter of the barrel, and having at equal distances on its circumference three semicircular ears projecting beyond its circumference. Another plate of a similar form is cast separately, with a central hole sufficiently large to fall over the circular part of the barrel, rather smaller than the main part of the same. The sheave being cut on its two surfaces to the figure of these flanches, by the means described below, the coak is first introduced on one side, and its flanch applied to the figure cut on the surface of the sheave to a proper depth to receive it: the detached flanch is next applied on the other surface to the barrel, and then rivetted as hereafter described. Form of the coak.

(377.) It appears, therefore, that what remains to be done to complete the sheave for receiving the coak, is to countersink its surface to the figure of the flanch on each face, and this is effected by what is called the coaking engine. The operation is performed by fixing the sheave horizontally on a frame which admits of its being placed in any degree of eccentricity with respect to a vertical spindle carrying the cutter, but still in such a way that the three ears must be at precisely equal distances from each other, and from the general centre. The sheave being properly adjusted, a very rapid rotation is given to the spindle and cutter, and a circle is thus cut in the place of one of the ears; the sheave is then turned a third of its circumference round, the exact measure of which is marked and limited by the construction of the engine, when a second circle is cut, and then a third, all to exactly the same depth, which is also determined by a pin properly fixed for the purpose; and lastly, the sheave being fixed centrally, the larger circle from which the ears proceed is cut in a similar manner, this latter circle passing very nearly through the centres of the former. And this process being gone through on the other face, the sheave is completed for receiving the coak. Coaking engine.

The coaks are formed of gun metal, cast in sand from accurate patterns, made for the purpose in the usual way; the only peculiarity which requires to be mentioned is, that the core which is inserted in the sand for forming the hole through its centre is not a smooth cylinder, but has two projecting threads which wind round it spirally in the manner of a coarse screw, so that when cast, the interior surface of the central hole through the coak has spiral cavities or chambers winding round within it, in the manner of the spiral cores of a rifle barrel; but these do not reach to the ends of the hole, which is smooth and circular to form proper bearings. These recesses are intended to contain a supply of grease to the centre pin when the block is in use.

(378.) The next process the sheave undergoes is to have the coaks rivetted in, which is performed by a small rivetting hammer, worked also by the Machine with great rapidity. This does not require any very minute description; it acts after the manner of the usual tilt hammer, but in consequence of the rapidity of the motion, the hammer would not fall with sufficient rapidity to be clear for the succeeding cog of the wheel, if left to the Rivetting hammer.

Manufac-
tures.

mere action of gravity; it acts, therefore, against a spring which facilitates its descent and gives an additional intensity to the blow. In using this Machine, the workman takes a sheave, and, lifting up the hammer, applies it beneath the face of it; then, by shifting the band or strap, which is all the time in motion, from the dead to the live pulley, the axis is put in rotation, and the hammer beats upon the rivets, so as effectually to fasten them in their places. It should be observed that the rivetting is, of course, on the surface having the detached flanch, and by the process the barrel of the coak is slightly shortened, whereby the flanches are drawn into the recesses with such force as never to be again in danger of getting loose. But to make every thing more secure, pins are sometimes inserted through small holes drilled in the centre of the semicircular ears and through the sheaves, which, being also rivetted at each end, gives, of course, additional security; but it does not appear that this process is necessary, nor is it frequently had recourse to.

Broaching
engine.

(379.) The next operation is that of broaching the coak, it being, as far as we have hitherto described it, only in that state in which it is received from the founder. This is done by what is called the broaching engine; the sheave is fixed on a flat chuck, at the upper end of a vertical spindle, which revolves while the borer is forced down perpendicularly through the centre hole of the coak, thereby forming a truly cylindrical and truly central hole, the centricity being secured by the manner in which the sheave is fixed to the spindle. To effect this the spindle is hollow for a considerable depth down it, and the borer is a cylindrical rod which exactly fits into this hole in the end of the spindle, and also fits pretty truly into the centre hole of the coak in the state in which it comes from the rivetting hammer. This cylindrical rod has a small tooth of steel fixed into it, projecting a small distance from the circumference, that is, to the distance to which the centre hole is to be enlarged.

The sheave is, of course, fixed on while the Machine is at rest; while in this state the broach is drawn up by the same screw movement which forces it down when at work, so as to get it clear out of the end of the spindle; the sheaf is then laid upon the flat chuck at the upper end of the spindle, which is larger than the sheave itself. The cylindrical borer is next put down through the centre of the sheave, and entered into the hole in the end of the spindle. By this means the sheave is placed on the chuck, exactly in the centre of it, and both being flat, it only requires to be screwed or clamped fast against the chuck, so as to be turned round at the same time with it. This is done by a clamp, consisting of an iron ring of a smaller diameter than the sheave, having two short bars projecting from the opposite sides of it. These bars extend across the face of the chuck, to which one of them is connected by a joint or hinge, and the other by a screw; or in other words, the clamp may be considered as one bar, having a large hole through the middle of it, one end being hinged to the chuck, and the other drawn towards it by a screw similar to a vice screw, but is so constructed as to be quickly unhooked, and then the clamp bar may be lifted up upon its joint, in the manner of a book lid, to place the sheave under it. The ring or hole through the centre of the clamp, when screwed down upon the chuck, is concentric with the spindle, and thus leaves the centre of the sheave free and clear for the operation of

the borer. The sheave is thus, by means of this clamp, Machinery fastened down upon the face of the chuck in a moment, and the workman sets the Machine in motion. He now, by turning a handle, gives motion to a wheel over head, in the centre of which is a nut, through which the screw in a line with the borer is fitted to work; and this screw, as well as the borer, being prevented from turning round by appropriate fitting at the end of it, is caused to descend, and force the borer down till its cutting tooth meets the bell-metal coak, and cuts its way through, enlarging the hole to its intended dimensions, and making it truly cylindrical to fit the pin on which it will turn when in the block. It has been observed that the interior surface of the hole has two spiral grooves or cavities withinside of it, which are formed in the casting as before described. These are too deep to be taken out in the broaching, and form receptacles for grease, which is thus always kept supplied to the centre pin, both to diminish friction and avoid wear of the parts. This is a great improvement in the blocks, as without such receptacles the pin well fitted into its centre hole, as it is and should be, would afford no room for grease, and then the block would require constant attention to keep it supplied, or would always be in want of it.

(380.) It still remains for us to describe the last operation Facing the sheave has to undergo, viz. the facing and turning the groove for the rope to run in on its edge. This is, in fact, only a lathe, but it is fitted in a most ingenious way to answer its intended purpose. The sheave is fixed to the mandrel by its centre, and a slide rest carries the tool which turns the face; the motion of this cutter, which proceeds from the centre to the circumference, is not perpendicular to the axis of motion, but a little inclined so as to form the face somewhat convex, in order that when placed in the block, it may only touch at the centre, thereby avoiding any unnecessary friction. The motion of the slide rest is governed by the Machine; the facing process requires, therefore, no attention from the workman, except that as the motion for turning gun metal requires to be much less than that for turning wood, as soon as the cutter has passed from the centre to the extremity of the face of the gun metal flanch, the workman, by shifting the band to another pulley, doubles the velocity of rotation while the tool is cutting the wood; and while these processes are going on upon the face of the pulley, the workman in the usual way, with a gouge and common rest, forms the groove for the rope on the edge of the sheave. The face on one side being formed, the sheave is reversed, the second face turned, and the entire operation thus completed.

(381.) All now remaining to be done is to form the pin Pin turning on which the sheave turns. The pins are first forged in a lathe. way not differing from the usual practice, between two swages by two workmen, and rendered thus as truly cylindrical as possible, consistent with the operation of the forge hammer, but at each end they are left for a short distance square to be inserted into the cheeks of the block, that the pin may not turn round by the friction of the sheave when it is put together. The lathe for turning the pins is fitted for this one particular object, and has every motion and all its arrangements most ingeniously contrived; but in its general principle it does not differ essentially from another lathe intended for turning iron, and, therefore, we do not think it necessary to enter into a minute description of it.

The pin thus turned to a truly cylindrical figure has

Manufactures.

Pin polishing Machine.

still another process to undergo, which is that of being polished, whereby it acquires a most perfect surface, and becomes compressed and hardened, so as to reduce the friction to the least possible quantity.

(382.) The Machine used for this purpose consists of three steel dies fixed in a box, and regulated by strong screws to form a triangular opening of any required dimensions. The pin being drawn through these dies, and turned round at the same time, receives a very violent pressure and friction which burnish and polish the whole surface in the most perfect manner imaginable. The dies are, of course, immersed in oil to avoid the heating of the pin or dies by the friction. The pin is fixed, by means of a strong hand vice, to the lower end of a long screw, with which it forms a right line; this screw and pin are fixed in a vertical position exactly over the dies, and the screw is enclosed in a nut or female screw, which is made in two halves, and shuts up after the manner of a pair of tongs round the screw, so that it can be opened and the screw raised or lowered at pleasure, it being properly suspended and balanced by tackle, which furnishes the means of lifting it with ease. Exactly beneath the screw are fixed the dies, these being fitted into an iron frame or box containing the three, each fitted into a proper groove, and adjustable by a screw behind it, to form a triangle of such dimensions that the pin shall exactly fit it. The interior surfaces of these dies are highly polished, and rendered as hard as possible, and the frame in which they are fixed is, as above stated, immersed in oil.

Conceive now the screw at the top of its movement, and the pin fastened to it by the vice above described. One of the screws at the back of one of the dies is now screwed back, enlarging the opening, and admitting thereby the pin. The nut on the screw is now opened, and the pin let down till its square end comes to the dies. The back screw is now brought up to bite the pin, and then closed round the screw. The Machine being now put in motion, and the screw turned round, the pin is also turned round as it is drawn up through the dies, whereby the surface is burnished in the most perfect manner; so that when it comes out it has as high a polish as it is possible for iron to bear, and the surface receives a kind of case-hardening which is very advantageous, as it enables it to bear the friction to which these pins are exposed without any sensible wear or abrasion.

We have thus endeavoured to describe the nature and operation of this series of highly ingenious Machines, the performance of which, through the obliging introduction of the inventor, we have witnessed with satisfaction and admiration; but we are still much indebted, in several of the preceding explanations, to the original descriptions and drawings of Mr. Farey, who in Rees's *Encyclopædia* has illustrated the several operations with numerous figures and plates in a most complete and masterly manner.

Common bellows.

(383.) *Blowing Machines.*—The most simple Machine of this kind is the common bellows; but these, considered simply in relation to their application to domestic purposes, would hardly claim a place in the list of Machines falling under our description; but their use is much more extensive, as in the cases of forging, founding, and general smithing, as well as in organs and other pneumatic instruments. Bellows are constructed of various forms and sizes, according to the nature of the duty they are intended to perform, and furnished with

different kind of apparatus to give them motion, and to force the air from their interior. Beckmann, in his *History of Inventions*, dedicates some pages to the subject of bellows; observing, that after the discovery of fire it is probable the bellows, in some shape or other, soon followed, and he therefore gives them a very early origin; for we can hardly suppose men were long created before either natural effects or accident led to a knowledge of that universal element.

Our common bellows, which consist of two boards joined together by a piece of leather, and which are probably an imitation of the lungs, appear to have been known to the early Greeks; but of what kind of bellows they availed themselves for smelting, forging, &c., is not known. Strabo informs us, on the authority of an old Historian, that Anacharsis, the Scythian Philosopher, invented the bellows, the anchor, and the potter's wheel; but this account is very doubtful, as Pliny, and other authors who have also spoken of the inventions of this Philosopher, mention only the two last, and not the bellows. Leaving, however, these early claims in as much doubt as we find them, it is pretty certain that in the oldest smelting-houses the bellows, such as they were, were worked by men; and such places are still indicated by the refuse of the furnace, where at present, for want of water, such works would not be erected. Bellows of the larger kind, such as those in smitheries and furnaces, formed of leather sides, required very careful management, a constant attention to oiling, &c., inconveniences which first gave rise to wooden bellows.

(384.) These, except the pipe, consisted entirely of wood. The whole Machine was formed of two boxes, placed the one upon the other, the uppermost of which could be moved up and down upon the lower one after the manner of the lid of a snuff-box, having a hinge; but the sides of the uppermost box were so broad as to contain the lower one between them, when raised to its utmost extent: both boxes were bound together at the smaller end by a single hinge bolt, and here also was placed the pipe. It may easily be comprehended that when both boxes fitted each other exactly, and the upper one was raised over the under one, which was in a state of rest, the space included by them would be increased, and that air would rush in through the valve in the bottom of the lower one, and when the box was again forced down this air would be expelled through the pipe. The only difficulty is to prevent the air which forces itself in from escaping any where else than through the pipe; for it is not to be expected that the boxes could fit each other so closely as to prevent entirely the air from making its way between them. This difficulty, however, was obviated by the following simple and ingenious method. On the inner sides of the uppermost box there are placed movable slips of wood, which, by means of metal springs, were pressed to the sides of the other box, and filled up the space between them. As these long slips of wood might not be sufficiently pliable to suffer themselves to be pressed close enough, and as, though planed perfectly straight at first, they would, in time, become warped in various directions, incisions were made in them across through their whole length, at the distance of fifteen or eighteen inches from each other, so as to leave only a small space in their thickness; by which means they acquired sufficient pliability to be every where pressed close enough to the sides to make them sufficiently air tight for the purpose.

Beckmann says that the invention of these wooden

Machinery

Wooden bellows

Manufactures. bellows, which are still in use on the Continent, is certainly due to the Germans. Grignon expressly affirms this; and in Becher's time they were not in use in England, although they were in the former Country: the name of the inventor, however, is not known. It appears that about the middle of the XVIth Century an artist, Hans Lobfinger, who resided at Nuremberg in 1550, furnished the Magistrates of that city with a catalogue of his Machines; from which catalogue it has been concluded that he understood the art of making large and small bellows, both for organs and for melting-houses, and likewise copper bellows, which produced an equable blast of wind; and Beckmann concludes, that as Lobfinger made organs, he himself perhaps was the inventor of the bellows he constructed, but what their actual form was is not known. Agricola, who died in 1555, makes no mention of wooden bellows; so that these appear at all events to have been an invention of about this date, or a little later.

Blowing Machines. (385.) These kind of bellows, however, if they have any existence at present on the Continent, are, we believe, wholly out of use in England; where their place has been supplied by Blowing Machines of the most varied form and construction. In our larger works the blowing Machines are commonly large iron cylinders, worked by pistons, like the steam engine. In some cases three or more cylinders, from four to five feet in diameter, and in length a little more or less than their diameters, with a piston fitting air tight, are placed over or in connection with a large iron wind chest, so that as the piston is forced down by the action of the steam engine or water wheel, the air which was previously in the cylinder is forced into the chest through a valve opening into the same. On the return stroke the air enters into the cylinder below the piston, and is again forced into the chest on the descending stroke, where, as above stated, there are two, three, or more such cylinders connected with the same chest. The strokes of the several pistons are made in succession, and another cylinder is generally attached, which serves as a safety valve or regulator, its piston being free, and loaded with a certain pressure per square inch, or per square foot, according to the nature of the blast which is required. In the Blowing Machine in his Majesty's Dock-yard, Woolwich, there are four cylinders, and the pressure per square inch is a quarter of a pound; when the pressure exceeds this the piston is raised by it, and the air escapes. From the air-chest pipes are connected with all the forges and fires in the smithery, and the air is let on the fire by turning a cock, in a manner very similar to that of turning on water with the common water-cock. The valves here are all of the sliding kind, and the Machine works so quietly that a person might sleep without being disturbed, even in contact with the cylinder.

At Messrs. Crawshaw's iron works. In a very large Blowing engine we have seen at Messrs. Crawshaw's works at Merthyr Tidvil, the valves are placed in the piston opening inward; these are closed by the internal pressure when the piston is descending, but open and admit the air on the ascending stroke; these valves being what are called clack valves, the silence we have remarked in the former Machine must not be expected in this construction. In another Blowing Machine on the same premises, the reservoir for the compressed air is a large iron globe eighteen feet in diameter, which, from its great capacity, preserves the pressure very constant, as it will of course admit several cubic feet to be removed without experiencing any very sensible diminution of elasticity.

Machinery. Another Blowing Machine, or perhaps bellows, the writer has seen at Messrs. Brunton and Co's. iron cable manufactory, which is exceedingly simple and neat. Here a beam, resembling the beam of a steam engine, has a rod suspended from each end, and to the lower end of each of these is fixed a hollow iron vessel of considerable capacity, with its opening downwards; this just reaches to the surface of a quantity of water in a cistern; under the centre of each vessel is an iron tube rising a little above the water, and each vessel is supplied with a valve opening inward. When, by the action of the steam engine, one of the vessels is forced down, the valve shuts by the internal pressure, and the air is forced through the tube or pipe above-mentioned. During this down stroke, the vessel on the other side has been rising, receiving at the same time a supply of air through its valve. This now descends, and delivers its charge of air down a corresponding tube, while the former has made its ascending motion and received a fresh supply, to be discharged again at the next stroke, the same as in the first instance.

Various other kinds of bellows or Blowing Machines might be described, but we shall confine our remarks to only one or two others. Forge bellows are sometimes made to work by means of the reciprocating or oscillating motion of a large cask or vessel, suspended on an axle lengthwise, with a vertical partition from end to end, open at its bottom part; each half being supplied with a valve, a quantity of water filling about one half is now put in, and the vessel is inclined; by this means all the water is found on one side of the partition; the valve on the empty side opens by the pressure of the external air, and, therefore, one half (the lowest) is filled with water, and the upper side with air. If now the barrel or vessel be made to incline on its axis the contrary way, the water passes under the bottom of the partition, and as it occupies the space before filled with air, it drives the latter before it through the tuyau which passes to the furnace or forge; during this process the valve in the other half opens, and the place of the water is supplied with a charge of air, which in its turn is driven out by the next inclination of the vessel. It is obvious the partition we have spoken of needs descend but little below half the depth of the vessel; if it is made to descend too low, it would check the motion or passage of the water from one side to the other.

At Messrs. Sharp and Roberts's engine manufactory at Manchester, there is a powerful Blowing engine of very simple form. It consists of a large external cylinder of nine feet diameter and nine feet long, with an internal cylinder of the same length and of two feet diameter; these are concentric, and between the outside of the inner cylinder and the inside of the outer, are introduced four leaves or spires, which make exactly one revolution in the nine feet length. This is placed in a reservoir of water with its axle level with the surface at one end, and so inclined as to dip to within about two feet of its upper edge at the other end. The axle of the Machine being put in motion by the steam engine, the radial edge of the descending leaf reaches the surface of the water and thereby incloses a certain quantity of atmospheric air, which, as the motion proceeds, is carried along the cylinder till it escapes behind into its reservoir; and as this happens every time each of the four leaves reaches the surface of the water a continual stream of air is obtained, with perhaps as little friction and loss of power

Boring
Machines.

as possible. Some little but very little of the air does escape in front; the Machine is, however, very powerful and effective.

(386.) *Boring Machines*.—These are of various kinds, according to the nature of the material, and the purpose for which the substance when bored is intended to be applied, some articles requiring much greater accuracy than others. We have in our alphabetical arrangement slightly spoken of the process of boring as performed in the case of ordnance and steam cylinders, both of which, but more particularly the latter, require very great accuracy; so great that, in the finishing process, it is by many makers thought essential to keep the Machine continually at work, from the beginning to the end of the operation, through meal-times, day and night; for if it were discontinued while the cutter was only midway or in any part of its journey, and the cylinder allowed to lose the heat it acquires by the friction of the cutter, &c., a ridge and unevenness would be found in the surface which would be highly injurious to its proper action. In the boring of guns, although they scarcely require so much accuracy as steam cylinders, and are also much smaller in the bore, yet much of the present precision in artillery practice is due to the accuracy with which the boring of our ordnance is conducted. Formerly guns were cast with cores, and all that was attempted was to broach them to a certain size. In this way it was almost impossible to get a straight bore, and balls much smaller than would have been otherwise necessary were obliged to be used to give them any chance of reaching the charge: this allowed of great windage, much of the force of the powder escaped, and any thing but precision was attained in the direction of the projectile. This method has been practised in Turkey and other Eastern Countries to this day, but a proper boring apparatus is at this time being erected in Constantinople, which will of course supersede the old and inaccurate method hitherto practised. This consisted, as already stated, of casting the gun with a core; the gun thus formed was placed vertically between sliders to give it a proper direction, its muzzle was placed downwards, and the boring tool vertically beneath it. The latter was then put in motion by horses walking round it in a horse-mill, and the pressure or weight of the gun urged it forwards as the tool cut away the material. With such means the little value of the Turkish artillery may be easily accounted for. At present, however, the Sultan is erecting one of the most complete foundries in Europe for brass ordnance, and two most perfect boring engines are on their way from England to Constantinople, which will no doubt greatly improve the Turkish artillery.

In boring steam cylinders, a powerful and very accurate engine is required. The cylinder is placed horizontally and fixed in its position while the cutters are made to revolve and advance forward by the action of some powerful first mover, generally either a large water wheel or steam engine, and the operation is commonly repeated three times, in the last of which the greatest care is required, and in which, as has been already stated, the engine is continued in motion from the beginning of the operation to the end.

Ordnance have been bored in two ways; in one, the gun revolves and the borer advances, and in the other the gun was fixed and the cutter made to revolve. The former, however, is always adopted in brass guns, and as the gun revolves, its exterior surface is turned, which

is a great advantage, for in this way the bore is necessarily central and the face of the muzzle perfectly square with the bore of the piece. These processes have been already explained in the article referred to above.

(387.) *Machine for boring wooden pipes*.—Before the very general introduction of iron for forming water pipes, the boring of wooden pipes for this and for similar purposes was a mechanical operation of some importance, and, accordingly, different ways of effecting the object have been proposed and are described by different writers. A Machine of this kind is given by Belidor, where the tree to be bored is mounted on a carriage and well secured in its place. A vertical spindle, put in motion by a water wheel, driven by means of a trundle and face wheel, gives a rotary motion to a horizontal bar, carrying at its extremity a borer or auger; as this is made to revolve, motion is given to another wheel, about the shaft of which a rope is attached, which is also fixed to the carriage bearing the tree, so that, as the borer cuts its way, the carriage is gradually drawn towards its work till the hole is cut through. The carriage being now run back, a larger auger is introduced, and this operation is repeated till the bore attains the requisite diameter.

In other cases, the tree is made to revolve and the cutter remains still, except being advanced against the tree after the manner we have described in boring ordnance, but of course with less attention to accuracy, which is not in this case very essential. In some cases the tree is placed vertically, as also the borer, so that as the work proceeds the chips necessarily fall out as they are cut, which is attended with some convenience. It is obvious, however, according to all these methods, the part of the timber excavated is destroyed, namely, converted into chips; and this consideration has given rise to a very ingenious Machine, whereby the core is cut out whole, and is of course applicable to other useful purposes. This consists of employing a hollow cylinder armed at its extremity with a circular saw of the trepanning form; the cylinder being put in rotation by proper Machinery, the saw cuts its way and the core enters the hollow of the cylinder as the latter advances, and is thus preserved whole. It will not be necessary to describe this process more particularly, as in the following article a similar Machine is explained, which may be made applicable not only to boring wooden pipes but also to the formation of stone pipes and columns, such changes being made in the saw as the different materials may require.

(388.) *Boring Machine for forming stone pipes*.—This is an ingenious Machine invented by Mr. Murdock, who took out a patent for it in 1810, and by it the inventor also forms round pillars of stone. It consists, indeed, of a method of cutting out from a piece of a stone a solid cylindrical core, consequently the forming the cylinder is as much a part of its operation as that of making the hollow within, and when the first cylinder is large enough a second core may be taken out, so that little or no waste of material takes place except about half an inch round the core in which the tool acts. The method of performing this operation is shown in pl. xxx. fig. 3, and is described by the inventor as follows.

First, the block of stone is set upright or nearly so, and in the centre of the intended pipe or cylinder is placed a plug of wood or iron Z, having in its centre a hole to fit the pivot of the perpendicular axis or spindle A A. This spindle is considerably longer than

Manufactures.

Machinery

the pipe or column to be formed, and of a size proportional to the nature of the work. This is either triangular or square, or feathered, so that the tube which has a like formed perforation may slide down upon it at the same time that it is put in rotation by it. Upon the upper end of the spindle is fixed a hollow socket B, which fits tight upon the spindle, and on the centre of this socket is fixed a pulley *cc* or toothed wheel, by means of which it receives its rotary motion; the upper and lower parts being cylindrical to serve as gudgeons on which it turns, in a fixed frame of iron, wood, or other material. Near the lower end of the same spindle is attached a wheel or cross J J, shown also in fig. 4, with arms, having a hole in its centre which fits the spindle, and the circumference of this wheel or cross is made like a hoop, two, three, or four inches deep, its diameter a little exceeding the core to be cut out, and fits to the inside of the tube L L, so that the latter may slide easily over it. This is made fast to the spindle by a screw or key, but may be taken off at pleasure. The tube L L may be of iron, brass, or copper, and is of course a little less in its external diameter than the inside diameter of the pipe, while its interior diameter a little exceeds the exterior diameter of the central core, and to its lower edge is fixed the saw or cutter for forming the cut, which, ultimately, separates the core from the exterior part, thereby forming the intended pipe.

The tube to which this cutter is fixed, is connected with the axis or spindle by means of a second wheel or cross *k k*, which is fixed by its circumference to the inside of the tube, having a hole in its centre which corresponds to the figure of the spindle, and slides freely upon it, so that the tube may be slipped up or down the spindle, but always remaining concentric with it. To one of the arms of this cross is fixed a small cord, (or it may be a chain rod or rack,) which passes upwards through a hollow in the axis of the spindle, and, in case of its being a rope, over a pulley fixed at a convenient height; it then passes from that pulley to a windlass to which it is attached. The use of this is to raise or lower the tube upon the axis, which may be done even while it is in motion. The weights N N are for pressing the cutter downwards, and must be of course proportioned according to the nature of the work to be performed. The pulley or pinion *cc* is fixed upon the socket which receives the upper end of the axis, and is generally made about twice the diameter of the tube.

When the apparatus is to be put in motion by the force of men, a rope E E is wound round the pulley *cc*, the ends of the rope then pass over two other pulleys F F, only one of which is shown; the ends then turn downwards, and having handles attached to them, they are pulled alternately by two men, one on each side the spindle, whereby is obtained a rotary reciprocating motion which is found much more efficient in sawing stone than a continuous motion. S is a cistern furnished with a cock which supplies the inside of the tube with water, which by its pressure forces itself under the saw, carrying away with it the stone and sand which have been used in the process, in the form of mud, over the top of the block of stone under operation.

The method of applying a similar Machine for boring wooden pipes is obvious. In this case, the tree is best placed vertically above the spindle and cylinder, as this position admits of the dust falling out of the saw kerf as the operation proceeds.

(389.) *Calender and mangle.*—We combine these two

articles, because, although receiving different denominations they are the same in principle; the calender being but a larger sort of mangle, or the mangle a smaller sort of calender. The calender is employed in the dressing new goods, and the mangle for domestic purposes after washing, &c. In dressing cloth, two different processes are adopted. In the first such a degree of compression only is employed as is sufficient to remove any creases or folds which the cloth has previously received, and at the same time so to compress the surface as to render both sides smooth, uniform, and level. The second, besides effecting this, adds a gloss to one side of the cloth; the former is generally called dressing, the latter glazing.

The original calender for dressing cloth consists of a large, strong, and smooth bed of wood, or metal, or marble, and a large case also of wood or metal resting on it upon wooden rollers, the case being made very heavy by being filled with stones, lead, or other heavy bodies; this weight sometimes amounting to some tons. The goods to be calendered are carefully wound on these rollers, and are then placed upon the bed with the weight above mentioned resting upon them; one of these rollers is near one end of the calender or case, and the other about the middle; then as the large box or case is drawn alternately from one end to the other of the bed, the rollers become alternately situated at the end and middle. When the operation has been carried on long enough, the calender is easily tilted, or will tilt of itself on the centre roller; the other roller is then removed, a new one introduced till the case is again tilted at the other end, when the second roller is removed and replaced.

The calender is drawn backwards and forwards by two ropes, one fixed to each end of the case, which are wound and unwound alternately upon an axle, and the work may be performed either by men, horses, or steam power, water wheels, &c. when the Machinery is properly arranged for the purpose; but without some means especially contrived to avoid it, it is necessary to invert the motion of the handle to give the alternate motion to the case as above described. This is effected in various ways, but one of the neatest is that employed in Baker's patent mangle.

(390.) This consists in having an axle and pinion so fixed, that the latter acts upon the teeth of a face wheel, which occupy only the segment of a circle instead of the circumference, and the pinion is made to act first on one side of these teeth, and then on the other. Supposing, for instance, the leaves of the pinion are first acting inside the face teeth of the segment, and that while thus acting the mangle moves to the right. At the end of its journey the pinion will have reached the extreme tooth on the segment, and by continuing the motion of the axle the pinion would move on, but it is here caught by an arc formed on the segment wheel round the end of the teeth, and turning on this arc it is guided to the outside of the teeth, and the motion continuing, it now acts on the outside and drives the wheel back, till it arrives at the other extremity of the teeth, when it is again caught by a similar arc and turned inside; so that by a continuous motion of the handle a reciprocating motion is given to the mangle, which is furnished with a fly wheel to assist the pinion over the ends of the teeth as above described. Moreover, as it is obvious the pinion must in such case have some play, the axle is so arranged as to allow this, the pinion being kept to its

Baker's mangle.

tures.

Calender.
Pl. xxx.
Fig. 4, 5.

work by contact with the top or bottom of the space cut to allow this play, *i. e.* by its upper part during the action of the pinion, on one side of the teeth, and by the lower during its action on the other side.

(391.) Other means are employed in the larger calenders, but it will be unnecessary to describe them, as the best and most general sort of calender employed in our larger Manufactories are of a cylindrical form after the manner of the rolling mill. A calender of this kind commonly consists of five cylinders; as represented in pl. xxx. fig. 5. These are fixed in a strong wooden frame A, consisting of strong upright posts connected at the top by a strong cross piece, fixed to the upright posts by screw bolts, besides which there is usually another cross rail below secured in the same manner. Of the five cylinders shown in the figure, those marked *b, d* are of cast iron turned very smooth and hollow in the centre for the purposes of admitting cylindrical pieces of hot iron when the calender is to be heated. The main cylinder *c* was formerly of wood, but being very liable to split by the heat employed, this is now generally made of compressed paper, which is found to answer much better, and to be most economical, although the first cost is considerably greater. The advantages of this paper cylinder consists in the perfect smoothness that can be given to the surface, and in its having no tendency to either warp or split, to both which evils the wooden roller is very liable. The upper and lower cylinders, technically called *bowls*, marked *a, e*, are generally of iron or wood, of the same diameter as *b, d*.

For the common smoothing operation of the calender, it is only necessary that these five cylinders should be made to revolve on their respective axles, the motion of each having an inverse direction to that of those with which it is in motion, and the motion must be in the inverse ratio of their diameters, so that there may be no rubbing between the surfaces. The motion is transmitted from the moving power by a belt passing over the pulleys at D, the one being fixed upon the axle of the main cylinder *c*, and the other a loose pulley. Thus when the belt is upon the fast pulley, the calender will be in motion, and when it is shifted to the loose pulley, the calender will stop without interrupting the motion of any other Machine acted upon by the same power.

The large cylinder *c* being set in motion, the iron cylinders *b, d* receive their motion by means of the wheels C C, worked by the wheel B, on the axle of the large cylinder. The cylinders *a, e* will work sufficiently accurate by their friction with *b, d*, or their motion may be rendered certain by two other wheels pitching into the teeth of the wheels C C. Standing in front of the calender, the operation may be described as follows. The cloth coming from behind above the uppermost cylinder *a*, it passes between *a* and *b*, passing behind *b* it comes to the front between *b* and *c*, between *c* and *d* it is again carried behind, and lastly brought in front between *d* and *e*, where it is received and smoothly folded on a clean board or in a box, by a person placed there to receive it.

Here, in fact, terminates the operation of the calender; but the cloth has still to be pressed and packed, and it may not be amiss to describe the remaining part of the process. In folding the cloth at this time, care must be taken that it may be done very loosely, so that no mark may appear till it is again folded into the precise length and form into which the piece is to be made up. The

folding is done either by two persons or by one, with the aid of two sharp polished spikes placed at a proper distance to ascertain the length of the fold and to make them all equal. When thus folded into lengths, it is again folded across upon a smooth clean table, according to the shape intended, which varies in different kinds of goods.

In general, it is desirable to have goods well smoothed and folded so as to occupy as little bulk as possible in packing. When the pieces have received the proper folds, it is necessary therefore to submit them to a heavy pressure in order to compress them as closely as possible. This is commonly performed by placing a certain number of pieces, divided by thin smooth deal boards, in a common screw press of great power. Besides the wooden boards, a piece of glazed pasteboard is placed above and below every piece of cloth in order that the outer folds may be as smooth and glossy as possible.

The common screw press, however, since the ingenious invention of the hydrostatic press, has been generally superseded by the latter in most large Manufactories; but as this press and its application to different purposes will be described under its proper head, we shall not enter into an explanation of its operation in this particular case.

The calender above described is applicable to the stronger and heavier sort of goods. Lawns, muslins, and goods of a light fabric undergo a similar sort of process in a smaller Machine, which has only three rollers, and as the goods require to be only well smoothed, but little pressure is required, the Machine works lightly, and the work is commonly performed by a man at a handle or winch fixed to the axle of the middle roller. In these calenders the middle roller is a very smoothly turned iron cylinder, the other two are of wood, and the Machine is always worked cool. Book and mull muslins, which are finished with starch at the bleaching, to give them a clear and wiry appearance, receive no other finishing at the calender than folding and pressing. And on the other hand, some goods, before passing through the calender, have to be singed; an operation which requires great care, as the whole surface of the piece is passed over a semi-cylinder of red-hot iron, in order to destroy the rough woolly nature of the surface. In this process a steady uniform motion is requisite, for if the motion be too rapid, the operation will be very unequally and imperfectly performed, and if too slow, the piece is immediately destroyed; such accidents, however, but seldom occur after the operator has acquired confidence by a little practice.

(392.) In fabrics of thick cloth, including both those kinds which are used for many household purposes, and those for the dress of females, the operation of glazing is used both to add to the original beauty of the cloth, and to render it more impervious to dust or smoke. The glazing operation is performed entirely by the friction of any smooth substance upon the cloth; and to render the gloss brighter, a small quantity of bleached wax is previously rubbed over the surface. The operation of glazing by the common plan is very laborious, and the apparatus is of the most simple kind. A representation of it is given in fig. 6, 7. A is a table, with a thick stout cover of level and well-smoothed wood, forming an inclined plane, that side where the operator stands at work being the lowest, and is generally placed near a wall, as represented in the figure, both for convenience in suspending the glazing apparatus, and for

Machinery

Glazing.
Fig. 6, 7

Manufac-
tures.

the sake of light. A long piece of wood B is suspended in a groove formed between two longitudinal beams D D, placed parallel to the wall, and fixed to it. The groove resembles exactly the aperture between the sides of a common turning lathe. The lever B, of which the groove may be supposed to be the centre or fulcrum, is faced at the bottom with a semicylindrical piece of finely polished flint C, which gives the glaze to the cloth stretched upon the table below. Above the flint are two cross handles B B, of which the operator lays hold, and moves them backward and forward with his hands, keeping the flint pressing slightly upon the cloth. When he has glazed a portion equal to the breadth of the flint C, he moves his lever between the shears D D, and glazes a fresh part; thus he proceeds from one side or selvage of the cloth to the other, and when all which is upon the table is sufficiently glazed, he draws it over, and exposes a new portion to the same operation. To preserve the cloth at a proper tension, it may be wound smoothly upon a roller or beam, revolving upon its own axis, and behind the table another roller to receive the cloth may be placed before both, being secured by a catch, acting in a ratchet wheel.

Glazing
calender.
Fig. 8.

To save a great part of the labour employed in glazing cloth, the common five bowl calender has been altered to fit this purpose, and upon some years' trial has succeeded to the satisfaction of those who use it. It is still confined to the extensive calender works of the late Mr. Miller of Glasgow, and was the invention of his superintendent. A profile view of this Machine will be found in fig. 8. It consists of five bowls or cylinders, like the common calender, but instead of the bowls revolving with a velocity in the inverse ratio of their respective diameters, so as always to present an equal surface, and to act merely by their pressure against each other, the bowls or cylinders *b* and *d* move with greater velocity than the bowls *a*, *c*, and *e*, and thus create or generate friction at three several parts of the operation. This difference is produced merely by the addition of a few wheels; and the difference between the common and glazing calender will be seen at a single glance, by comparing the wheel-work of fig. 5 and 8. In fig. 5 the motions of all the cylinders is in the inverse ratio of their diameters, so that each presents an equal surface. In fig. 8, the motion, instead of being directly communicated from *c* to *b*, as in fig. 5, is given by the intervention of two additional wheels. The increase of motion depending entirely on the relative number of the teeth in the wheels B and C on the axes of the cylinders *c* and *b* to each other, (for the intermediate wheels E and F merely communicate the motion without affecting the velocity,) *c* is made to revolve considerably quicker than in the common calender, and thus the necessary friction is created. To change the glazing to the common calender, it is only necessary to remove the wheels E and F entirely, and to substitute a larger wheel for the wheel B, which may be calculated to work directly into the wheel C. The profile view given in this figure affords an opportunity also of showing the way in which the cloth is conducted from the table H over the roller I, through the calender, and received again at G. This is common to both calenders. A patent for Scotland was taken for the glazing calender; and upon a trial of some years, it has met with the entire approbation of those who have been in the habit of having their goods glazed

by it. As one Machine, by being worked day and night, Machinery is capable of glazing nearly 1000 pieces of cloth of twenty-eight yards each in a week, it is peculiarly adapted for the occasional hurry to which shippers are sometimes unavoidably subjected. Brewster's *Encyclopædia*.

(393.) *Capstans, crabs, cranes, and other Machines* Original form of the capstan. *for raising heavy loads.*—These are of various forms, indeed they are too numerous for us to attempt any thing like an individual description of them in this Work; at the same time some general account will be necessary. The invention of the capstan is of very questionable date; it appears that it was first used in British vessels during the reign of Elizabeth, but it was in use before that time in the Spanish and Portuguese service. The capstan in its original form is exceedingly simple, consisting only of an upright barrel or drum turning on a vertical axle; on the upper part of the drum is fixed the capstan head, with holes or sockets sunk in the same for receiving the capstan bars, which project about ten or twelve feet, and to these (generally eight in number) the strength of men is employed to urge the capstan round, the weight being raised by means of a rope winding round the barrel. In this simple form, however, great inconvenience is experienced by the necessity of always keeping the power applied to prevent the weight running back; and obvious as the means are which are now employed for preventing this recoil, it was many years after the capstan was known that these were introduced. The French Royal Academy first saw the necessity of some improvements in this useful Machine, particularly in its application to naval affairs, and proposed the subject as a prize Essay. This led not only to great change in the methods of *palling* the capstan, which had before been introduced, but also to great changes in its form and manner of acting. The falling palls now generally used in the common, and indeed in all kinds of capstans, was the invention of Lalande, the celebrated French astronomer. These palls are commonly attached to the lower part of the barrel turning on a pivot, so as to rise as the capstan is urged forward over any obstacle, after which they fall by their own weight into steps of iron made to receive them, and which, in case of any recoil, checks, in the most effective manner, any retrogradation of the weight or purchase; but when it is necessary to reverse the motion, the palls are turned over on their pivots, when they act as effectively in the opposite direction.

In the first rude form of the capstan the barrel was plain and cylindrical, and great difficulty was experienced in surging the rope, or as it is termed on ship-board, the messenger. The barrels are now furnished with additional pieces securely fixed to the barrel, called *whelps*, and the capstan head is securely bolted down, as well to them as to the barrel, and these being trimmed slightly conical, greatly facilitate the surging of the rope, which is thus received and delivered without rising or falling from its proper place.

This simple form of the capstan and its power are too well known to require any further illustration in this place. The power, of course, depends upon the length of the bar, or rather on the distance of the centre of pressure on the bar, and on the radius of the barrel, including the whelps and half the thickness of the rope. When only one man is working at a bar, the power with which he pushes, multiplied by the distance from the axis, will express the effect of his power; and this,

Manufac-
tures.

when there are several bars multiplied by the number of them, will be the whole power, and this is equal to the weight multiplied into the radius of the barrel; but when there are several men to a bar, the centre of all their positions at each bar must be accounted the centre of pressure; in other respects the calculation is the same.

Phillips's
capstan.

It has been stated, that a variety of forms has, within these few years, been given to the capstan. One by Captain Phillips, Royal Navy, has been somewhat largely introduced into the British Navy; this is called a power capstan, as it is made to gain by wheelwork a power of four to one. This Machine is described under the article Capstan, in our general alphabetical arrangement.

Smith's
power cap-
stan.

Another power capstan has recently been invented by Mr. Smith, and is introduced into some merchant vessels, which has the advantage of avoiding the use of the capstan bars, being worked by a crank or winch, which is an object of great importance in trading vessels, particularly in steam vessels engaged in conveying passengers; for the winches may be placed either fore and aft, or transversely from the capstan to the ship's side, without interrupting or abstracting from the convenience of the persons on board when in use, and when not wanted for actual service, they are removable the same as the capstan bars. In this Machine the head of the capstan is furnished with a strong bevelled wheel, in the teeth of which works an endless screw on one side the capstan or on both; the endless screw is worked, as above stated, by a winch which has a bearing at the other end in the ship's side, so that several men may work at once, and the power gained by the endless screw being very considerable, fewer men are requisite to work this capstan than to work the common one, and certainly by dispensing with the capstan bars it allows of more cabin room or more stowage; but unfortunately its friction is very great, and, of course, in this, as in all other mechanical constructions, what is gained in power is lost in time, so that the operation of this capstan may perhaps be found too slow.

Eckhardt's
capstan.
Pl. xxxi.
Fig. 3.

(394.) A different sort of power capstan has been proposed, in which the power gained is almost unlimited, but it is not fitted well for naval purposes; this is the invention of Mr. Eckhardt, and may answer equally well or better as a crane. This is represented in plate xxxi. fig. 3, where A D is a compound barrel consisting of two cylinders C, D of different radii. The rope D E C is fixed at the extremity of the cylinder D, and after passing over the pulley E, which is attached to the load by means of the hook F, it is coiled round the other cylinder C, and fastened at its upper end. A B is the bar by which the compound barrel C D is urged about its axis, so that the rope may coil round the cylinder D, while it unwinds itself from the cylinder C. Let us now suppose that the diameter of the part D of the barrel is 21 inches, while the diameter of the part C is only 20, and let the pulley E be of any diameter. It is evident that when the barrel A D is urged round by a pressure exerted at the point B, 63 inches of rope will be gathered upon the cylinder D, and 60 inches will be uncoiled from the cylinder C by one revolution of the bar A B, these numbers representing the circumference of each cylinder. The quantity of wound rope, therefore, exceeds the quantity that is unwound by 63 - 60, or 3 inches, the difference of their respective perimeters; and the half of this quantity, or $1\frac{1}{2}$ inches, will be the

space through which the load or the pulley E moves by Machinery. one turn of the bar. But if a simple capstan of the same dimensions had been employed, the length of rope coiled round the barrel by one revolution of the bar would have been 60 inches, and the space described by the pulley or load to be overcome would have been 30 inches. Now, we know in Mechanics, that the power of any engine is universally equal to the velocity of the impelled point, divided by the velocity of the working point, or to the velocity of the power divided by the velocity of the weight, that is, to the velocity of the point B divided by the velocity of the pulley E; consequently, if the lever in both capstans be the same, and the diameter of their barrels equal, the power of the common will be to the power of the improved capstan as $1\frac{1}{2}$ to 30, that is, inversely as the velocity of their weights, and the power of the latter will be $\frac{30}{1\frac{1}{2}} = 20$, or in other words, will be equivalent to 20

fold tackle of pulleys. If it be wished to double the power of the Machine, we have only to cover the cylinder C with laths a quarter of an inch thick, so that the difference between the radii of each cylinder may be half as much as before; for the power of the capstan increases as the difference between the radii of the cylinders is diminished. As we increase the power, therefore, we increase the strength of our Machine, while most other engines are proportionably enfeebled by an augmentation of power. Were we, for example, to increase the power of the common capstan, we must diminish the barrel in the same proportion, supposing the bar or handspike not to admit of being lengthened, and we not only weaken its strength, but destroy much of its power by a greater flexure or bending of the ropes.

The reader will perceive that this capstan may be converted into a crane or windlass for raising weights, merely by giving the compound barrel A B a horizontal position, and substituting a winch instead of the bar. The superiority of such a crane above the common one is obvious from what has been said; but it has this additional advantage, that it allows the weight to stop at any part of its progress without the aid of a ratchet wheel and catch, from the two parts of the rope pulling on contrary sides of the barrel. The rope, indeed, which coils round the larger part of the barrel acts with a larger lever, and, consequently, with greater force than the other; but as this excess of force is not sufficient to overcome the friction of the gudgeons, the weight remains stationary in any part of its path.

A crane of this kind was erected in 1797 at Bordenton, in New Jersey, by Mr. M'Kean, for the purpose of raising logs of wood to the frame of a saw-mill, which was 10 feet distant from the ground. The diameter of the largest cylinder was 2 feet, and its length 3 feet; the other cylinder was 1 foot in diameter, and of the same length with the largest. The difference of their circumference, therefore, was 3 feet, and the log would move through a space of 18 inches with one turn of the handspike, and through the required height with only 8 turns. The length of the bar or handspike was 6 feet, which, at the point where the power was applied, described a circle of about 30 feet, so that the power of the crane was as 1 to 20. The length of the rope was only 55 feet, whereas if the weight had been raised through the same height with a similar power, by means of a tackle of pulleys, 270 feet of rope must have been employed.

Manufactures.

Windlass.

In the latter case, however, the rope sustains only one-twentieth of the weight, and in the former it supports one half of the load. *Ferguson's Lectures* by Brewster.

(395.) *Windlass*.—This may be considered as a horizontal capstan; in the latter Machine the barrel is generally placed vertical; when placed horizontally, whether it be worked by a winch as in the common erections over wells, or by movable bars, as on board vessels, it is called a windlass. The latter Machine on shipboard is commonly placed forward, the capstan always aft. The ship windlass consists of a horizontal barrel turning on an axle in two fixed sides with holes or sockets for receiving bars or handspikes by which it is worked. One man, for example, having introduced his bar about six feet in length in a hole nearly vertical, steps up, and, seizing it as high as he can reach, throws himself backward, and as it advances he presses with greater and greater weight upon it till he brings it horizontal; this brings some other hole or holes vertical, into which another man inserts his bar, and thus the windlass is made to revolve, winding a rope about its barrel precisely as in the common capstan, except that here there is a perpetual shifting of the bars, whereas in the former they remain fixed during the operation; the bars are also shorter and the power considerably less, not only in consequence of the bars being shorter, but because fewer men can be employed. This kind of windlass pulls itself by means of a falling pall upon a wheel with proper shaped teeth for the purpose.

Crane.

(396.) *Crane*.—This is also a Machine, in its common form very well understood; it is used for raising heavy loads in a vertical direction, and is therefore furnished with a long projecting gib or neck, which, from its supposed resemblance to the long neck of the crane, has thereby derived its denomination. The simple crane which we see attached to the sides of warehouses is a simple gib of this kind, which sometimes, when not in use, is shut close back against the wall; this gib carries a pulley, over which a rope is passed to a windlass, and the other to the weight to be raised. When it is brought to its proper height, the crane is swung round to bring the load close to the door into which it is to be received, and being landed on the floor, the crane is again swung out, the rope descends, and another weight is raised, and so on. The cranes on the sides of wharfs are similar in principle, but frequently more powerful. These are made to turn on a long vertical axis, which descends to a considerable depth in a proper recess sunk to receive them, and left so that a person may descend to supply them with oil, &c. Some variety of cranes have been described under that article in our alphabetical arrangement, and various other kinds may be seen in almost every Work on Mechanics, their forms being almost infinite, and the modes of working them also very various. Formerly, walking wheels were very commonly employed for working cranes, and even horses and asses have been thus made to do the duty. They may also be worked by horses as in a horse mill, but more commonly they are worked by men at winch handles, and commonly in the better sort of cranes there is the means of engaging different powers, and an apparatus for swinging the crane round when the load has been raised above the level of the wharf.

Sometimes the waste power of a steam engine is employed in working cranes, and this on two different principles, one by the compression of air in a strong vessel, and another by exhaustion or by rarefying the air in a receiver; the power to give motion in the latter

being the pressure of the atmosphere above that of the Machinery. air in the exhausted receiver, and in the other by the excess of pressure of the condensed air above that of the atmosphere. Both of these are patents, the former by Mr. Wright, and the other by Mr. Hague, engineer and millwright of Ratcliff.

Mr. Wright employs for his purpose what he calls a reciprocating rotary engine, by which compressed air, admitted from a reservoir, is to work the crane. This consists of a flat iron cylinder, in which a piston, made to occupy the place of the radius, turns round an axle, placed in its central line, through the whole space between that line and the circumference. A partition is fixed across in one part of the cylinder from the centre to the periphery, which confines the motion of the piston to a single revolution in each direction at one time, or obliges it to "reciprocate," as it is called, round from one of its sides to the other alternately; a tube passes from the reservoir of compressed air to the extremity of this partition, where it enters a cock with two ways, which forms a communication with this tube, and the different sides of the partition, and also with the latter and an eduction pipe, according as it is turned; in one position letting the compressed air press at one side of the piston, so as to force it forward in that direction, while it leaves open a free passage between the air at its other side and the atmosphere through the eduction pipe; and in the other position, causing the compressed air to act on the side of the piston opposite to that on which it first operated, and leaving the communication with the atmosphere open at the side where the compressed air before entered.

On the axle round which the piston turns, and to which it is fastened, a crank is formed outside the cylinder, which by a connecting bar acts on a similar crank attached to the axle of a pinion, the teeth of which interlock with those of a large wheel that is fixed to the barrel of a crane of the common species; and a fly wheel being placed on the axle of the pinion, by its momentum makes the motion this receives from the crank of the air engine be continuous, instead of being alternately reversed, as is that of the latter crank, and thereby turns round the barrel. Two other revolving air engines are likewise described in the patent, which may be applied to the same purpose as that mentioned; one of which is similar to the rotary steam engine for which Mr. Wright obtained a patent in October, 1825, an account of which is given in the third volume, second series, of the *Repertory of Arts*.

(397.) Mr. Hague proposes as the actuating force for working his cranes, the pressure of the atmosphere operating on a piston in an oscillating cylinder, (see Art. 206.) to whose opposite side a communication is opened with a vacuum or partial vacuum, made in a vessel of proper form and capacity, communicating by means of a long tube with an exhauster worked by an air pump attached to the beam of the steam engine in any part of the establishment.

The crane itself that is to be worked by this method is of the common sort, in which a cord or chain is wound upon a horizontal cylinder, that is made to revolve by a series of toothed wheels, ultimately urged by a pinion; and the force mentioned is made to work this crane by having a crank formed in the prolonged axle of that pinion; to which crank the piston rod of the air cylinder above mentioned, (after being properly supported by a cross head and guides fastened firmly to the latter.) is

Wright's method of working cranes.

Hague's method of working a crane.

Manufac-
tures.

connected by a joint constructed like others of the same description. A fly wheel is also fastened to the end of the same axle, to equalize the action of the crank; and the communications between the different extremities of the cylinder with the atmosphere and the vacuum vessel are alternately reversed by means of a cock with four ways, which communicates with two passages formed in one of the gudgeons of the air cylinder, one of which passages is continued to the top of the cylinder and the other to its lower extremity; this gudgeon has a conical termination, on which a conical cap is pressed by spiral springs, which keep the junctures air tight, while, through openings made in it, the operation of the cock is conveyed to the cylinder, as above stated, according to the direction in which it is turned, by means sufficiently resembling those employed with other cocks of the same sort, not to require here the particular description that is given in the specification.

The gudgeons of the air cylinder are supported on blocks below the barrel of the crane, and from its cock with four ways, a pipe descends downwards to the vertical metal pivot, on which the crane turns; this is made hollow for its reception, and moves in an air-tight box, from which another pipe ascends to the vacuum vessel; which arrangement permits the crane to turn round laterally in the usual manner, without interrupting the passages necessary for the air apparatus.

Much similarity will be observed between the two methods of working last described, both acting by means of the pressure of the air moving from a denser to a rarer medium; but as Mr. Wright employs air compressed beyond the pressure of the atmosphere, while Mr. Hague employs the pressure of the latter only pressing on a partial vacuum, the difference in principle is sufficiently obvious, and there are, we conceive, some differences in the advantages. Mr. Hague's plan does not require such strong vessels as Mr. Wright's, and will be kept air tight with more facility, because the pressure of the atmosphere, which is the operating force used, acts externally in closing and compressing all their parts together; but when the power of his engine is limited, as it can never amount to a force of fifteen pounds on each square inch of his piston, on account of a perfect vacuum being practically impossible. Mr. Wright's method will on the other hand require very strong vessels to retain the compressed air, being more liable to leak as well as to burst, from the pressure acting on them internally; but it will have the advantage of as great a force being employed with it as may be thought proper, or one amounting to several multiples of atmospheric pressure; its reservoir may also be considerably smaller than the vacuum vessel of the other apparatus, (which must be very large, to prevent the pressure on the piston of the air cylinder from diminishing too rapidly,) a circumstance that may save expense, and economize space considerably.

Bramah's
method of
working
cranes.

Another principle or method of working cranes, is by hydrostatic pressure. This method, if not first proposed by Mr. Bramah, was perfected by him, and it has been applied to several powerful cranes, but is not, we believe, very generally adopted. The simplest form of this application for a Machine to raise a heavy weight to any height, is to have the iron gib, of the usual kind, properly fixed at the required height, furnished with the usual pulley or wheel, over which the rope or chain passes, and thence over another pulley over the shaft or upright leg of the crane, which, descending to the barrel, is wound

up by the following contrivance. The hydrostatic cylinder is placed in a vertical position exactly as in the hydrostatic press described in a subsequent page under the word Press, or it may be laid horizontally or in any inclined position; the end of the piston rod is furnished with a long toothed rack which works in the teeth of the pinion on which the barrel is placed, so that when the piston is raised by the pressure of the water from below, the rack turns the pinion and barrel, which, winding up the rope or chain, raises the weight to any required amount within the limits of the Machine, which of course may be varied in any proportion by different length of rack and diameter of pinion.

This hydrostatic principle has the same advantage as Mr. Hague's method last described, viz. that it can be easily transmitted to any distance, and in any direction, by means of pipes conducted along in situations where all other means of conveying the motion would be complicated and expensive in the extreme; thus, in an extensive range of warehouses for a dock or depot, an injection pump may be kept in constant action by horses, a water mill, or steam engine, and may inject water into an air vessel, from which pipes are conducted to cranes in all parts of the works; and by simply opening a cock at any crane, the required load will be instantly raised by the elasticity of the confined air on the enlarged surface of the piston of the crane. The air vessel has, of course, a safety valve, to allow the escape of the water when the pressure becomes so great as to endanger the rupture of the vessels; for it is to be observed, that the power of this principle is irresistible when the pump is worked by a mill, and will burst any vessel without the appearance of strain on the moving parts of the pump.

(398.) *Crab* is a name given to a Machine for raising loads, which is a portable winch and barrel worked by wheel and pinion work, fixed in a cast iron or heavy wooden frame, which may be transferred from place to place wherever its duty may be required. When used, as it frequently is, for raising the weight of the pile engine, it is bolted fast down upon its base, and in other cases to sleepers, or to a heavy wooden frame, to give it a firm standing: it is of very simple construction, which will be immediately understood by reference to fig. 1, 2, pl. xxxi.

Crab.
Pl. xxxi.
Fig. 1, 2

(399.) *Gin* is another Machine employed in raising large stones and other weights, and in artillery practice in lifting large guns on to their carriages, &c. The latter differs a little from the former. It is composed of three long and stout legs, meeting together at their tops, these legs are round poles of about twelve or thirteen feet long, whose diameters at the lower end are about four or five inches, and about three and a half inches above.

Two of these poles can be fixed at a certain distance from each other, by means of two iron bars placed horizontally, one being about four feet long, the other about seven; and a roller is made to run upon pivots turning in cheeks attached to two of the poles; this roller is commonly seven or eight inches in diameter, and six feet long. A portion of twenty inches is left square at each end, and holes made in each to receive the handspikes by which the men turn the roller, but the middle part is made cylindrical, to wind the rope upon it. The transverse iron bars are fixed with one end to one of the poles by means of a bolt, and with the other end to the other pole with a bolt and key, so as to be readily taken out, in order that, when the gin is to be moved from place to place, the poles may lie close

Manufactures. together upon the carriage. There are two iron bands and two iron bolts to fasten each cheek to the poles, for the pivots to revolve in, and iron plates round the poles where the iron bars are fixed. The poles are hooped at each end; and the upper ends have straps through which an iron bolt passes: this bolt keeps the upper ends together, as well as serves to support the block through which the rope passes to the windlass. The block contains two brass pulleys, about which the rope goes, which is fixed to the dolphins of the gun or mortar with another block, containing two brass pulleys likewise. When this Machine is to be used, the whole is laid flat on the ground, the lower end of the single pole extending the contrary way, in order to fasten the upper block after the rope has been turned round both; after this the upper end is raised gradually till the feet of the three poles (each of which has an iron prong) stand nearly at equal distances.

The common gin differs from the above only in not being furnished with a windlass.

Jacks for raising weights. (400.) *Jack* is a name given by English mechanics to a simple kind of Machine employed in lifting great weights to small heights.

Lifting jacks are of three kinds: the hand jack, or jack in the box, which, as we shall see, is worked by a rack and pinion, the screw jack, and the hydrostatic jack.

Pl. xxxi. Fig. 4. *Hand jack*.—This, as we have stated, depends upon the purchase or power gained by the rack and pinion, which will be, of course, proportional to the length of the winch and the radius of the pinion. In pl. xxxi. fig. 4, this Machine is represented in its improved form, having a pall to prevent the descent of the weight in case of the hand being removed from the winch handle, a very important, although a very recent improvement. The whole Machine consists of a block of wood about two feet six inches long, ten inches broad, and six inches wide, is perforated with a square hole or mortise through it lengthwise, for the reception of an iron rack B. This rack is formed with a double claw or horn at its upper end. A small pinion C is made to engage in the teeth of the rack. The axis of the pinion is supported in iron plates bolted to each side of the block, and one end of the axis projects through the side plate, with a square to receive a winch or handle, which being turned round, the pinion raises the rack B in the mortise, and, consequently, the claw or horn up to the load to which it is applied. To prevent the weight of the load running the pinion back, the handle is detained by a hook or link fastened to the outside of the block. When a greater power is required than the simple rack and pinion are capable of exerting, a combination of wheelwork is used, as shown in the same figure, where A A is the block of wood, which in this case is made sufficiently wide to contain the cog wheel F, fixed in the pinion C, which acts in the teeth of the rack B. G is a second pinion of four leaves, working in the wheel F, and the axis of this pinion projects through the side of the block for the winch H to be fixed on it. The block A A is made in two halves, and the recess for the wheel F and pinion G is cut out in one of the halves; the other being laid flat against it, supports the front pivots of the wheel and pinions. The two halves are bound together by strong iron hooks b b driven over the outside. The rack has a claw N at its lower end, projecting outside-wise through an opening or slit cut through, in the front half of the block. This claw can be introduced beneath

a stone which lies nearly flat upon the ground, and Machinery. which, consequently, could not be acted upon by the claw on the top of the rack. To prevent the rack descending when it has a load upon it, the small click a drops into the teeth, but clears it in going up; when it is not required to detain the rack, this click can be turned out of the way sidewise.

Fig. 5 is a screw jack. The block of wood A A is perforated nearly its whole length with a hole sufficiently large to allow the screw B to move up and down without touching. The screw passes through a nut n, fixed firm into the top of the block A; and if the screw is turned round, it must rise up through the nut, and elevate the claw F. This claw is fitted on the top of the screw with a round collar, which allows the screw to turn round without turning the claw; and the claw N, which projects through a groove or opening made in the side of the block, is fitted to the screw with a smaller collar. The bottom of the block has four short points to prevent the Machine slipping when used upon hard ground. To give motion to the screw, the lower half of it is formed into a square, and a worm wheel c is fitted upon the square. The teeth of this wheel are engaged by a worm on the axis of the winch H, and plates of iron a b are bolted on each side of the block, near the middle of its height, to carry the ends of the axis of the winch, and of the worm which is concealed behind the worm wheel c. When the winch is turned round, it causes the wheel c to revolve by the action of the worm in its teeth; and as the wheel is fitted on the square part of the screw, it compels it to turn with it, but at the same time allows the screw to move up and down.

The friction of this kind of screw jack is very considerable; nor is its strength so great as the screw jack shown in fig. 6, 7. In this the screw is not made to turn round, but only to rise and fall; and the worm wheel c being placed very near the top of the block A, has a nut for the screw B to pass through cut in its centre. By this means the nut is turned round instead of the screw, and it requires no collar either at the top or bottom of the screw. The axis of the worm, like the former screw jack, is supported by two iron plates a b, and the end which projects through the plate a is made square for applying the winch H. The worm wheel is shown dotted. The circular part D is a part of the wheel c, and forms a collar for the wheel, and gives also a greater depth of nut for the screw to work in.

Hydrostatic jack.—This is, in fact, a small kind of hydrostatic press, and, of course, very powerful in its action, but it is not so simple in its form as those above described; and it differs so little from the hydrostatic press explained under the article *Press*, that it will be only necessary to say here that the upper end of the piston is supplied with a claw like the common jack, instead of the pressing board or iron table; and as in this Machine the piston rods can have no guides, it is best to have the cylinders open at both ends, so as to admit the plunger to pass quite through, one end of which, i. e. the lower being considerably less than the upper; the pump also in this case is attached to the press, forming thus only one Machine.

(401.) *Copying Machines*.—In a mercantile nation like Great Britain, where such an extraordinary extent of correspondence takes place on affairs of business, not only amongst ourselves, but with all parts of the World, it is very desirable in many cases to take copies of letters and communications, which if effected by actual copying

Copying Machine. Fig. 11.

Manufac-
tures.

by hand would consume a deal of time, employ an inconvenient number of copying clerks, and in cases of confidential and important transactions, divulge matters which it may be desirable to preserve secret. To remedy such inconveniences, a variety of copying Machines have been invented, of which one of the most simple is that by Mr. Brunel. This ingenious Machine, which is a sort of press, is shown in pl. xxxi. fig. 11, where *a* is the bottom of the press, made of the best gun metal, and *b b* a pressing board of wood, having above it a steel plate spring *c c* which rests upon ledges and supports the pressing board by the screw *d*. A strong steel lever *e*, moving on the plane *f*, presses near its centre on the head of the screw *d*, and *g* is another lever moving on the joint *h*, to which the power of the hand is applied. A damping apparatus is necessary for moistening or rendering damp the letter to be copied; this is contained in the box *i*; it consists of a metallic cylinder having several sheets of fine linen rolled round it of the same size as the sheets of paper employed. In using the press the original letter is put into a transferring book, and a blank leaf of paper turned over upon it; a sheet of the damp linen is then laid upon the blank leaf and above that a leaf of oiled paper; the book being shut and introduced between *a a* and *b b*, the hand is applied to the lever *g* which presses down the lever *e* with great power, and communicates the pressure to the book by means of the knob *d* of the pressing board *b b*, and thereby imprinting on the oil paper a legible copy of the letter. It is of course inverted on the side next the latter, but on the other, from the transparency of the material, it is read direct.

Various other description of Machines for this purpose have been invented, and to prevent copying at all a Machine has been contrived to write two or more letters at the same time. It is, however, inconvenient in comparison with the simple process of copying.

Card-
making
Machine.

(402.) *Card-making Machine*.—Before we attempt to speak of the operations performed by this very ingenious piece of mechanism, it may be necessary to say a few words with reference to the card itself. In the cotton, woolen, and some other Manufactures, the material has to undergo a process called carding. This may be said generally to consist in passing the cotton, wool, &c. between cylinders, on which strips of cards are fixed lengthwise at certain distances from each other; these cards or strips consisting of short wires, something resembling the nature of a brush, made of fine iron wire instead of bristles. The wires, however, are not, as in a brush, inserted in bunches, but each stands single, being passed through a tolerable thick piece of leather, and placed so close as to present some hundred points in the space of a square inch; each wire is bent into a form somewhat resembling the staple to a door, its two ends penetrating the leather, and afterwards slightly bent in a general inclined position, in order to meet the work with more effect.

Hides of leather are cut up into strips, varying for different purposes in breadth, from two inches to six inches and upwards. These are passed between iron rollers, adjustable to different distances, and furnished with a sharp cutting edge below, by which, in the passage, the leather strip is shaved off in its thickest parts, and reduced to one uniform thickness throughout; its edges also are very exactly trimmed, to render the whole of one uniform breadth, at least for the same description of card.

These strips thus reduced are passed next to a workman, whose business is to join them end with end into a long length. This is done by placing the end under a strong pressure, leaving about an inch projecting, and this inch is, by means of a sharp broad knife dexterously applied, reduced to a perfect bevel of an inch in length across the breadth, the same having been performed on the end of the piece to which it is to be joined; a very thin solution of fine strong glue, made of acetic acid and isinglass, is applied, the two bevelled parts are placed on each other, the joined part submitted to a strong pressure, which completes the process, and when dry and slightly trimmed, if necessary, the union is formed so perfectly that it is scarcely possible to distinguish the place; a number of such pieces being united together in one length, the leather is fit for the operation of being manufactured into card by means of the Machine. In some Machines the leather is placed vertically, and is carried on upwards as the operation proceeds, but in others it is stretched horizontally. The process is the same in both; but it would require too many figures to illustrate minutely the nature of its action, which is exceedingly complicated and rapid, and displays extraordinary ingenuity. A hank of fine wire is put on a reel, turning horizontally at a short distance from the Machine, and the end of the wire introduced into the frame; the axle being now put in gear, the wire is carried forward about an inch, and is at the same time cut off to that length; two side pieces of steel now press on the sides, and bend the wire to the staple form; in the mean time two fine steel points are pushed forward to form two holes in the leather; these are below the two ends of the staple, and immediately they are withdrawn the wire itself is thrust forward into the holes, while a pair of nippers takes hold of the back of the staple and gives it that slight bend we have before described. The whole of these operations are performed in rather less than half a second, a slight adjustment takes place sideways after each, and thus the process is carried on till the card is completed.

It has been stated that the several operations of drawing on the wire, cutting it to its proper length, bending it to its proper staple form, piercing the leather belt with the two steel points, withdrawing these, bending the wire in its own plane, and inserting it in the card, are all performed in less than half a second; in fact, the mean action of the Machine is at the rate of 130 insertions per minute, the greatest number being about 150. Taking the mean, 260 holes are pierced in a minute, consequently 15,600 in an hour, and the working hours being eleven per day, each Machine pierces 171,600 holes per day, and consequently works up about half that number of inches of wire, or 85,800 inches. There are one hundred of these Machines in the Manufactory of Mr. Dyer of Manchester, which we have had the gratification of visiting. These hundred Machines will, therefore, use up 8,580,000 inches of wire per day, or to the amount of about $13\frac{1}{2}$ English miles. The cards being thus formed are fixed with their backs upon the cylinders above described, which of course prevents the wires from coming out. This, however, is done by the parties employing the cards and form no part of the card-making process. These being sent from the latter Manufactory in the state in which they are taken off the Machine above described.

(403.) *Counting Machines*.—Under this head are included several very ingenious contrivances, which are

Machinery.

Quantity of
wire used
in a day.

Counting
Machines.

Manufactures.

adopted for various purposes, and which it may be well to describe in this place. Such Machines are very useful for counting and registering the number of strokes made by a steam engine in a given time; the number of revolutions made by a carriage wheel while passing between two places, and consequently the distance between those places; the number of revolutions made by the wheel of a railway carriage, so that, by knowing the distance, the amount of slips and retrogradation may be ascertained. Thus, also, an account may be kept of the number of foot-passengers through a toll-way, and a like application may be made in various other cases.

Counting Machines for road carriages, or viameter

(404.) *Counting Machine for wheel carriages.*—A very simple and ingenious Machine for measuring the number of revolutions made by a carriage wheel is sold by Mr. Carey in the Strand. It consists only of a brass plate, having a fixed axis or pin placed perpendicularly to its surface, with an endless screw cut on its middle part. On this axis is suspended a small brass frame hanging freely, and which swings below the axis above named. In the frame are two small brass wheels, turning each freely and independently on the same axis, and each cut with teeth on their edges, bevelling towards each other, the one containing 100, and the other 101 teeth. The endless screw on the fixed axis, engaging in the teeth of each of these wheels, drives them in the same direction, every revolution of the carriage wheel moving them one tooth; for the frame being always kept suspended below the axis by its own gravity, the effect will be the same during the revolution of the carriage wheel to which the Machine is fixed, as if the endless screw itself had made one revolution, and consequently the wheels will each be moved forward one tooth.

In 100 revolutions the wheel with 100 teeth will have returned to its original position, but that with 101 teeth will be behind one tooth. In 200 revolutions the first wheel will have again taken its original position, but the second will be two teeth behind, and so on; so that the number of teeth the second wheel is behind the first will be a register of the number of hundreds of revolutions the carriage wheel has made since the carriage started, or since the Machine was set, and the number of revolutions the carriage wheel has made beyond some even hundreds, will be shown by the number of teeth the first wheel has advanced towards a complete revolution. Thus, for example, suppose the index or zero on the second wheel to have fallen back 72 teeth, and that the index or zero of the first wheel has advanced 37 teeth. This will show that the carriage wheel has made 7236 revolutions, and so on for any number of revolutions under 101 times 100, or 10,100, at which number both wheels will have attained their original position. Supposing the carriage wheel to be 12 feet or 4 yards in circumference, the distance the instrument will thus measure is 40,100 yards, or nearly 23 miles. If the distance exceed this, there is a small spring in some of these Machines which enables the experimenter to count one for three such complete revolutions. But this appendage seems unnecessary, and is more commonly omitted. The Machine will of course continue to count on again after the first 10,100 revolutions, exactly as it did at first; and, therefore, unless the distance was so great as to be likely to lead to a mistake of one complete set of 10,100 revolutions, or 23 miles, such appendage as we have spoken of is unnecessary. In a long voyage by a steam vessel some such means is desirable, and is described in a following article. The wheels above

spoken of are but little larger than a half crown, the circular plate which carries the fixed arm or axis is about the size of a common snuff-box lid; the whole is placed in a strong leathern case, with straps for buckling it to one of the spokes of the wheel, and it should be placed as near to the nave as possible, to prevent the suspended frame from acquiring a centrifugal force sufficient to cause it to overcome the force of gravity, which will of course interfere with its accuracy, this depending altogether on the Machine preserving its verticality during the revolution of the wheel.

(405.) *Counting Machine for measuring the number of strokes of a steam engine.*—We have seen a Machine of this kind, we believe the invention of Mr. Watt, which consisted of a series of very light brass wheels and pinions, the wheels having 100 and the pinions ten teeth, so that the motion is reduced from wheel to wheel one-tenth. Thus 10,000 revolutions of the first wheel will give 1000 revolutions to the second, 100 to the third, and 10 to the next. These wheels are fixed in a small box in one line, the pinion of the first wheel acting on the circumference of the second, and the pinion of this on the circumference of the third, and so on for a series of five, six, or seven very light wheels. This box is buckled or otherwise fixed on the beam of the engine, and a short heavy pendulum, resting on the bottom of the box, slides backwards and forwards at every inclination of the beam; this is so constructed that in sliding one way it engages the teeth of the first wheel, and urges it forward one tooth, but in the return stroke it passes back freely, in the next stroke it engages another, and urges on the wheel one other tooth, and so on. The wheels are all graduated, 0, 1, 2, 3, &c. to 9; and at the commencement all the 0's, are at the top of the wheels in a line, and at any time by looking to the figures shown on the upper part of the wheels, the whole number of revolutions will be indicated in their proper figures and values according to the usual numerical notation. The wheels and pinions are very light, so as to offer but little friction and resistance, and the weight sliding on the bottom of the box is of course such as to enable it in its descent to overcome both.

(406.) *Counting Machine for a toll-bar.*—This may of course be constructed on the same principle as the above as far as regards its registering, but requires to be much stronger. Here the rotations depend upon the turnstile, the pivot of which descends below the pavement, and the number of rotations may of course be counted by any system of wheelwork, which, in this case, is locked up. Moreover, it is necessary here to have a fall to prevent the Machine being turned back, and another to prevent its being urged forward more than one tooth for each passenger. This latter fall has a small iron paddle attached to it, which is above the roadway, and when this paddle is up, or the fall down, the turnstile is locked both ways; but when a passenger wants to pass, the toll man treads on the paddle, and raises the fall, which allows the Machine to advance; but the moment the person is through, his foot is removed, and the Machine is again locked. This is the general principle; the manner of carrying it into execution is quite at the pleasure of the constructor. Generally in such cases one Machine must be for passengers going one way, and one for those passing the other.

(407.) *Donkin's counting Machine.*—This Machine, as well as most others used for a similar purpose, depends upon the well-known principle of relative motion, which

Donkin's counting Machine.

Manufac-
tures.

the author observes may be exemplified by the three hands of a clock, in which one is a counter of seconds during the minute, and this last a counter of minutes during the hour, and the third of the hours through the day. The nature of the expedient had recourse to in this case, will, perhaps, be more readily understood by first stating that, in his Machine, ratchet wheels are employed, and that these wheels are moved one tooth at a time, by means of clicks appended to a lever; but instead of this first wheel gradually moving on a second, the second wheel is only moved forward one tooth at every complete revolution of the first wheel, and the third wheel one tooth at every complete revolution of the second wheel, and so on to any extent required. The Machine is a very complete one, but to render it perfectly intelligible a number of figures would be necessary. We must, therefore, be content to refer the reader, who is desirous of fully understanding its construction and the principle of action, to vol. xxxvii. of the *Transactions of the Society of Arts*, where he will find it fully and clearly described.

Roasting
jacks.

(408.) *Jacks for roasting*.—These are well-known domestic Machines, and are of three kinds besides the original form, which is now, we believe, quite obsolete. This was a wheel like a walking crane, of a small kind, in which a particular description of dog, called thereby the *turn-spit* dog, was trained to walk round like a man in a crane, by which means rotation was given to a wheel, which carried a band passing round another wheel on the spit, which was thus also put in rotation.

Smoke
jack.
Pl. xxxi.
Fig. 8

(409.) *Smoke jack*.—This is a very simple substitution for the labour of the dog. It is represented in fig. 8, where A A is the brickwork of the chimney, which is contracted to a circular figure at A A; B is a strong iron bar, placed upon an arch of brickwork over the fire-place, to form a support for the wheelwork of the jack; C is a horizontal wheel placed in the circular funnel A A; it is made of iron plates, with a number of vanes radiating from the centre, each being placed at an angle of about 30° to the plane of the wheel; the heated air which ascends the chimney will strike the vanes and turn the wheel; the lower end of the spindle D, on which the wheel is fixed, has a pinion E fixed on it, and turns a contrate or crown wheel F on the horizontal spindle G; on the other end of this spindle is a pulley H, for an endless chain, which descends to the spit on which the meat is placed; the pulley pinned on the end of the spit is laid in the loop formed by the endless chain, so that this chain at the same time suspends one end of the spit, and gives motion to it; the under pivot of the spindle D is supported in an iron bracket *m*, projecting from the inside of the chimney, and the lower pivot rests on the top of a standard *n*, which also carries one end of the horizontal spindle G; when the chimney requires to be swept, the wheel C is lifted out of its centre, to allow a boy to pass: these jacks are always in motion when the fire is kept up.

Fly jack.
Fig. 9.

(410.) *Common roasting or fly jack*.—The smoke jack, although exceedingly simple in its action, and convenient as regards its substance, is not suitable for any but large families, where there are necessarily large fires and chimneys. In smaller establishments, the fly jack was the more common appendage of a kitchen fire-place, till in its turn it has been nearly superseded by the spring or bottle jack.

The fly jack is represent in fig. 9, where A is the barrel on which the cord for the weight winds; the barrel is not fixed upon the main axis, which is shown by dotted lines. It slips round upon it quite freely in

the direction proper for winding up the weight; but is prevented from turning in the other direction by a ratchet concealed within the barrel near the cog wheel B. The cog wheel B is fixed fast on the main arbor, and its teeth turn a pinion *b* on one end of the arbor C; the other end of this carries a worm wheel, which cannot be seen in the drawing, but its teeth act in the worm cut on the vertical spindle T. On the top of the spindle is the fly wheel D, which regulates the motion of the jack, and prevents the main arbor from turning too fast by the power of the weight. A wooden pulley E is fixed on the main arbor on the outside of the frame for the endless chain *e*, which gives motion to the spit, and the pulley has several grooves to receive chains for two or more spits at the same time. Two legs or standards, I, K, are rivetted to the frame G, to fix the jack against the wall over the fire-place.

The weight for giving motion to the jack is generally suspended by a pair of blocks with two or three sheaves. The end of the line, or fall from the pulleys, is wound on the barrel A, and the weight is usually placed outside the house, and contained in a sort of chimney, to defend the lines of the pulleys from the weather. When pulleys are used, the jack will continue its motion longer without winding, but the weight must be much heavier than if it was simply suspended to the end of the cord.

When the weight is run down, a handle is applied to the square part *s* of the arbor of the barrel A, which projects through the frame H. By turning the handle round, the barrel goes with it, and winds the rope upon its circumference; but as the barrel slips round on the main arbor when the barrel is turned in that direction, the wheel B continues to revolve and carry the spit by the momentum of the fly wheel D, as long as is requisite to wind up the weight.

(411.) *Bottle or spring jack*.—This is an exceedingly neat and ingenious contrivance, and was the subject of a lucrative patent about forty years back. Its name of bottle jack is derived from the figure of its external case, which resembles that of a common wine bottle, and its name spring jack from its being put in motion by the action of a spring. No spit is used in this kind of jack, but the meat is suspended before the fire and the jack keeps it constantly in motion, by turning it round several times with a proper velocity, first in one direction and then in the opposite. The jack is suspended from a projecting sort of gibbet, attached above the fire-place, and which, turning on pivots like a wall crane, is laid back flat against the wall of the chimney when not in use. We are indebted for the following description of this ingenious little Machine to Mr. Farey, as given by him in Brewster's *Encyclopedia*. The jack is represented in plate xxxi. fig. 10, where A is the spiral spring coiled up in a box which is fastened to the frame. The interior end of the spiral spring is connected with the main arbor B, which is supported by the plates R S. On this arbor the wheel C, with its ratchet wheel *z*, is fixed, and turns the small pinion D on the second arbor E; at the end of this arbor the contrate or escape wheel F is fixed; and G is a vertical arbor with two pallets *a* and *b* projecting from it, the one engaging in the teeth on the upper side of the contrate wheel, and when the pallet *a* is not in action, the pallet *b* intercepts the lower teeth of the wheel. This is a crown wheel escapement, such as is used in common watches, and gives motion to the arbor G alternately in a backwards and forwards

Machinery

Bottle jack.
Fig. 10.

Manufac-
tures.

direction. On the lower end of the arbor G a sector *c* is fixed, and is cut into teeth at its circumference, to form a segment or portion of a wheel. It gives motion to the pinion H on the short vertical arbor *d*; and the wheel I is fixed on the same arbor to give motion to the pinion L in the centre of the jack, which is fixed on the vertical arbor *m*, and passes through the bottom plate of the bottle, and has the fly wheel O fixed to it, with the hook P for suspending the meat. The arms of the sector *c* are sufficiently extended to admit the arbor *m* between them. The arbor is sustained by the fixed cock *i*, and is also suspended by a number of small catgut strings going up through the centre of the jack to the top of the neck of the bottle, and attached to the cross pin *r*. These strings take off part of the weight of the meat which is suspended on the hook P, and diminish the friction on its collar. This effect is, also, partly produced by a small spiral wire spring *t* coiled round the arbor, and bearing on the cock *i*.

The spring jack is wound up by the key Q, when applied to the square part *s* of the main arbor; and in the act of winding, the great wheel C is not turned round by the ratchet wheel *z*, because the click fixed to the great wheel slips over the sloping side of the teeth. To prevent the spring from breaking, a pinion *n* is fixed on the end of the main arbor; beyond the plate it works into the wheel O, which turns upon a pin fixed into the side plate S of the frame. When the main arbor has made a sufficient number of revolutions to wind up the spring, the leaves of the pinion *n* come in contact with a part of the wheel O, which has no space in it, and this prevents the arbor being turned any further so as to endanger the breaking of the spring. The maintaining power of the spring, when wound up, gives motion, by the wheel C and pinion E, to the escape wheel F, the upper tooth of which meets with the pallet *a*, and carries it along with it, turning the vertical arbor round upon its pivots. This motion is communicated by means of the sector *c* to the pinion H, and its wheel I, and thence to the sector pinion L and the fly wheel, and consequently to the meat. The use of the wheelwork CHL is to make the meat turn round several times before the tooth of the wheel escapes the pallet *a*, and then the tooth on the under side of the escape wheel meets with the pallet *b*, and turns the vertical arbor G and the fly wheel back again, in a contrary direction to that in which it was before turned by the pallet *a*; because the under side of the escapement wheel is going in a contrary direction to the upper side, and when the under tooth of the wheel escapes from pallet *b*, the pallet *a* comes into action again from pallet *b*; and thus a continuous motion is kept up, first in one direction for a few turns, then in the opposite direction, and so on, till the maintaining power of the spring becomes exhausted, when it must be wound up again by the key. The tube resembling the neck of the bottle is to give length to the catgut strings before mentioned, and which, by their twisting and untwisting, perform nearly the same office as the pendulum spring in a watch, and make the fly wheel return back readily. The bottom *b* of the bottle is screwed to a flanch or projecting rim round the bottom of the bottle; by removing these screws, and taking out the cross pin *r* in the top of the neck which holds the strings, the frame containing the wheelwork may be withdrawn from the case *x x* to be repaired or oiled as occasion may require.

(412.) *Lathe*.—Is a well-known Machine used for turning wood, ivory, metal, &c.; the essential part of which is

a spindle or mandrel turning very truly, and a rest for supporting the cutting tool. The name lathe, or lath, is undoubtedly derived from the original form of the Machine, which consisted of a long lath or pole fixed by one end to the ceiling or wall of the shop, from the other end of which a cord passed over a pulley carrying the mandrel and passed thence to the end of a board or treadle, which, when pressed on by the foot, gave a rotation to the pulley. On raising the foot, the spring of the lath caused an opposite rotation, which was reversed again by the pressure of the foot; so that the lathe in this form worked like a drill, and the cutting of course only took place during each direct rotation. Some such lathes are still to be seen, but the general principle of their action is now a direct and continuous rotation, by means of a strap or band passing over a pulley on the mandrel. This rotation may be communicated from the axle of a steam engine, water-mill, horse-mill, or by hand; and in some one of these ways rotation is given in the larger and more powerful lathes for turning brass, iron, &c., but in the smaller sort of lathes, the rotation is given to the mandrel by means of a band passing round a pulley on the same, and a fly wheel fixed on an axle with a single or double crank worked by the foot of the turner. This is then called a foot lathe.

The lathe is perhaps of all Machines that which assumes the greatest variety of forms, but it may be generally described as consisting of a horizontal part called the bed, which is formed commonly of two parallel bars of hard wood or metal firmly united together, or of a single metal triangular bar. To this bed are attached two upright parts called puppets, the one carrying the mandrel and pulley, which is fixed in its place, and the other carrying the back centre, which is adjustable, sliding between the double bed or on the single bar, to which in either case it is accurately fitted. The purpose of this is to give a second bearing to the piece of wood or metal while turning, when this is of any considerable length, in other cases the single attachment of the piece to the mandrel is sufficient. On the bed also slides the rest for supporting the gouge or other cutting tool, this being adjustable as well with regard to distance as to height and position. The bed itself is either securely screwed or otherwise fixed to two immovable supports, or it forms of itself part of a heavy strong frame, either secured to the floor, or which is so heavy as to be rendered secure by its own weight. Under the bed is an axle with a crank; to the axle is fixed the fly wheel, with a groove for carrying the band which passes also over the pulley on the mandrel, and to the crank is hung an iron bar attached also to the foot-board, and by which motion is communicated to the fly wheel, and hence to the Machine. This general description, and some minutiae not alluded to above, will be understood by reference to pl. xxxii. fig. 1, 2, in which is represented a lathe of a very simple construction; a front elevation is shown in fig. 1, and an end view in fig. 2. S S S, fig. 2, is a cast iron side of a triangular form; the two forming the support of the bed and lathe are seen in fig. 1, two holes in the bottom ledge of fig. 2 are for admitting two iron bolts to unite the bottom of the two sides together, while the bed securely screwed down to the upper part combines the whole into one compact frame. The sides of the lathe are terminated on the upper part by flanches, and each face of the bed has corresponding flanches; these on both parts are well faced on their edges so as to ensure complete contact, and then bolted together with

Machinery

Modern
foot lathe.
Pl. xxxii.
Fig. 1, 2.

Original
form of the
lathe

Manufac-
tures.

proper bolts and nuts. The part *e* which rises above the flanches is also accurately shaped and filed, and against this the beds rest and are bolted and keyed together transversely; the inside and upper face of the two beds being very accurately filed and ground to true parallelism in order to furnish a perfectly smooth and steady support for the back puppet in whatever part of the bed it is necessary to employ it. A bolt with a square head *E* passes through the base of the puppet, and through an iron block under the bed of the lathe, where its end, with a screw cut upon it, is received by a nut, by means of which it may be securely fixed in any place assigned for it, and when necessary to give it a new position the nut is slackened, the puppet slid to its place, when the nut is again tightened and the puppet secured. The motion of the support for the rest *R* is managed nearly in the same way except that the puppet has a descending square block *b* to work between the beds to secure its perfect parallelism, whereas the support for the rest slides only on the face, and may therefore be turned in any direction, but it is fixed to its place after its position is determined exactly as above described for the back puppet. The front puppet is secured in its place the same as the back one, and when a lathe is well made it may, the same as the latter, be slid from one end to the other of the bed without any shake or undue tightness in any part; this is not, however, so necessary, as it remains a fixture when its place is once properly determined.

About half way up the side of the lathe is a square part, *g g*, fig. 2, on which slides another part *h h*, which latter is drilled and tapped for admitting the screw *t* with a steel-pointed end, fig. 1, for carrying the axle, the latter being countersunk at the end for receiving the points of support. By means of the screw *s* this sliding plate may be raised or lowered, and thus the centres brought to exact equal heights; moreover, by this means the band of the lathe may be tightened when it becomes a little slack.

On the square axle *c* is formed a single or double crank for working the lathe by means of the hanging iron bar *v* and foot-board *a*, for giving motion to the lathe already described.

The wheel *w* should be formed of cast iron, and on its rim should be cast a ring of lead; the wheel is first keyed square on the axle, and then its leaden rim turned in its place with three or four grooves of different diameters to correspond with a similar set of grooves on the wheel *w* attached to the mandrel axle, whereby the speed may be changed, but the band remain of its proper degree of tightness, in any two of the opposite grooves in the two wheels. The axle of the mandrel is supported as shown in the figure; viz. the front face of the puppet has a hole very accurately bored through to receive the axle, which is also accurately turned and then case-hardened, as is also the other end, which is countersunk to receive the steel point on the back screw *s'*, and which is so adjusted by the latter as to allow the axle to turn freely but without any shake: on the front end of the mandrel is an external screw *D* for receiving the chuck for holding the piece of wood or other material which is to be turned.

The back centre is differently arranged in different lathes. The method shown in the figure is certainly one of the best. The bar on which the centre is formed is square and rests diagonally in two half-square holes, over which caps are screwed, having also half-square

notches to embrace the upper half of the bar, and by Machinery. means of the nuts on these screws, perfect contact and fitting may be secured without rendering the motion of the bar too difficult. The screw *s''*, which is best left-handed, is fixed to the end of the square bar, and the nut in which it works, having two flanches at its end, falls into a half-round groove in the part marked *V*, which is covered by a similar piece, viz. one having a semicylindrical groove, and screwed down by nuts as described above for the square bar. A handle *h* is fixed to the back flanch by which the nut may be turned round, and as this is prevented by the flanches from advancing on the screw, the screw itself must recede or advance, carrying of course the back centre with it. This is a remarkably neat method, and admits of the most delicate adjustment.

It now only remains to describe the different chucks by which the body to be turned is fixed to the mandrel. These are very numerous, but some of the most simple are described below.

A chuck of wood is commonly used by mathematical instrument makers. It consists simply of a piece of box, or rather there are generally several such pieces about the lathe, having a hole bored in their end and tapped with a screw whereby they may be screwed upon the end of the mandrel, and then they are turned down to such size as to receive upon them any short brass tube on which work is to be performed; this is fitted on very slightly, and is easily removed when the work is completed. In other cases the end of the wooden chuck is turned with an interior cavity to receive any flat circular piece of brass which requires facing; indeed, all the brass work of instrument makers is performed in this way, and every chuck being preserved, the workman, when a new piece of work is presented to him, selects any one of his old chucks which requires the least alteration, and therefore that alteration is of course readily made. When a tube is longer than can be safely trusted to this single support, a plug of box is introduced into the other end and the back centre brought up to it, which is what is called turning between centres.

Sometimes chucks are formed of flat pieces of brass having a thick piece behind tapped and screwed on the mandrel, and having holes through the flat part by which a piece of wood which is to be faced may be screwed. Others are provided with three jaws which can be altogether caused to advance or recede from the centre by turning a screw so as to encompass a piece of work of any dimensions. This method of chucking is employed in forming all kinds of flat or hollow work, as cups, boxes, circular rings, plates, wheels, &c., which are therefore termed chuck-work, but articles of considerable length must be supported at both ends as above stated; generally, however, the fixing requires to be more secure than that above described for facing slight brass tubes. A very common method is to have a metal chuck screwed on the mandrel, having a square hole cut in its end, and the piece to be turned being cut to fit this square hole is driven into it; at the other end is drilled a small hole to receive the back centre, which is adjusted properly to it by the screw in the back puppet. In other cases the spindle has a chuck screwed to it having a conical point; this forms a support for the end of an arm projecting from the chuck, which intercepts a pin or arm fixed on the work, and by this means turns it round with the spindle.

It would be endless to describe the variety of chucks

Manufac-
tures.

Description
of different
locks.

or methods of holding the work adopted in different cases, these depending in a great measure upon the ingenuity of the workman to adapt them to the particular occasions he meets with; those, however, above described are the most common and generally the most convenient.

(413.) *Lock* is a name given to different constructions of mechanism for securing doors, gates, boxes, &c.; it also denotes a part of a canal in inland navigation in which vessels are received in order to be raised or lowered from one level to another; it is also used to denote that part of a musket, pistol, &c. by which the powder is fired, &c. The common door lock is a well-known instrument consisting of a strong bolt, which must be fitted in a proper bed or case affixed to the door. A great deal of art and delicacy are required in forming and varying the wards, springs, bolts, &c. of locks, and in adjusting them to the places where they are to be used, and to the several occasions and situations in which they are to be employed. Those placed on outer doors are called stock locks; on chamber doors, parlour and other inside doors, spring locks, and when these are inserted in the wood, mortise locks; others are called trunk locks, padlocks, &c. The construction of these are well known; it will, therefore, be sufficient here to say, that the principal parts are, first, the main plate, in which is the keyhole, and to this plate are attached the top hook, cross wards, bolt-toe, drawback spring tumbler, pin of the tumbler, and the staples; secondly, the cover plate, carrying the pin, main ward, cross ward, step ward; and thirdly, the pin hole, to which belong the hook ward, main cross ward, shank, bow ward, and bit.

The principle on which all locks depend is the application of a lever to an interior bolt, by means of a communication from without, so that by means of the latter the lever acts upon the bolt, and moves it into a staple or other recess whereby to secure the door or lid from being opened till the bolt is returned to its original situation by the same means as those by which it was first moved forwards. The security of locks, therefore, depends on the number of impediments which can be interposed between the lever or key and the bolt which secures the door, which impediments are called wards, and consist of short projecting pieces of iron with corresponding notches in the key to pass over them; and it is the number and intricacy of these which constitute or distinguish what is called a good lock from a bad one. If the wards do not, however, cover each other so as effectually to preclude the access of all other instruments besides the proper key, an object very difficult to effect, it is still possible for a mechanic of equal skill with the locksmith to open it without the key, and thus to render the door and lock insecure; and hence have sprung a number of ingenious contrivances, in which the above objection to the common lock is in a greater or less degree avoided. It will be impossible for us to enter upon a description of these several inventions, as they are exceedingly numerous, and would require many plates to illustrate their modes of action; we must, therefore, be content with referring the reader to those places where he will find every information that may be required. The volumes of the Society of Arts are very prolific in these kind of instruments, as will be seen by the following references: vol. i. p. 317; vol. ii. p. 187; vol. iii. p. 160; vol. iii. p. 163; vol. xviii. p. 239, 243; vol. xix. p. 290; vol. xxiii. p. 333; vol. xxxviii. p. 111, 205; vol. xxxvi. p. 116. These volumes all contain de-

scriptions of different locks, extremely curious and many of them very useful and ingenious. See also the third and eighth volume of the *Repertory of Arts*, Old Series, and other patent locks in several volumes of the New Series of the same Work. With this multitude of contrivances, most of them extremely ingenious, it is difficult to make a selection; but one amongst the earliest of them claiming particular merit is that invented by Mr. Bramah, and commonly distinguished by the name of its inventor, which must not be passed over.

(414.) *Bramah's lock*.—This is represented in pl. xxxii. fig. 3, 4, 5, 6. Here A represents the bolt fitted to slide on the metal plate B B C, by passing through a hole in the side C, which is turned up, as shown in fig. 5; the other end of the bolt is guided by passing under proper grooves in the lower side of the circular box D D, which is screwed to the plate B to confine the bolt down. It contains the whole mechanism of the lock, consisting of an anterior cylinder or barrel E E shown in the section fig. 5, with its appendages in perspective in fig. 6. This barrel is fitted to turn round within the box D D, the upper end *aa* being received into a cavity exactly fitting it, and the middle encompassed by a circular ring of steel plate *bb*, screwed into the box as shown in fig. 5, and one half shown at *b*, fig. 6. The ring enters a circular groove formed round the barrel, and thus confines it from having any other motion than a rotation on its axis, and this only by the aid of the key, as will be explained. The barrel has a hole through its centre, which is closed at bottom by a circulate plate F, screwed to it, and supporting the central pin G, which occupies the centre of the hole through the barrel; this centre pin guides the key in entering the lock. When the barrel E E is turned round by the key, it shoots the bolt A, by an ingenious contrivance explained in fig 4, an aperture being cut through the plate B B C to exhibit it. The plate F, on the lower end of the barrel E, has a pin *f* projecting from it; this pin enters a curved opening at a small distance from the centre, and therefore describes a circle when the barrel is turned round, cut through the bolt A, as is shown by the curve F in fig. 4. In the position there shown the bolt is withdrawn, and the pin *f* resting against the solid part of the groove, prevents the barrel being turned round any further in the direction from F to *f*; but by the application of the key, the barrel may be turned in the other direction from *f* to F, in which course it passes round in a circular part of the groove, and therefore produces no motion of the bolt A, until the pin *f* strikes the straight part *g* of the groove and acts against it to throw the bolt forwards; and when the barrel has made a complete circuit, and the pin *f* is again come to the same position it had at first, the bolt is shot out as at fig. 3, and the pin is resting in the hollow *b*, which prevents it moving any further in the same direction. When the barrel is turned back again, the pin *f* acts against the notch *i*, and the curved part *k*, of the groove, and withdraws the bolt into the position of fig. 4; now the pin *f*, either when the bolt is shot out or in, is in a right line with the centre of the barrel E, to which it is fixed, and the direction of the bolt's motion. By this means, no force whatever applied to drive back the bolt can have the least tendency to turn the barrel round, and strain the mechanism which prevents its motion, unless the parts are first put into a particular arrangement by the application of the key. The interior mechanism must be explained by fig. 6, in which *l*, *m*, *n* represent small steel sliders, which are fitted

Machinery.

Bramah's
lock.
Pl. xxxii.
Fig. 3, 4, 5, 6

Manufactures.

into proper grooves or slits, made in the substance of the barrel E. Of these there are six in number, arranged round the barrel, and projecting a little from its exterior surface in the small part. These sliders are received in notches *y z* in the fixed steel ring *b b*, before described; and thus effectually detain the barrel at six points from being turned round, except it is first unlocked by the key R being introduced at the keyhole H, and the slider pressed down by it, so as to bring the notches (of which each slider has one, as at *r*, fig. 6) all opposite the steel plate *b b*, and then the barrel may be turned round. When the key is absent, the sliders are raised up by a brass ring *v* sliding on the central pin G and lifted up by a spiral spring *w*. The key has six notches cut in the end of it, as shown at S, which is an end view: each notch in the key includes one of the six sliders *l, m, n*, and the key being forced down into the keyhole H, depresses all the sliders at once, until the projecting leaf *t* of the key stops upon the bottom of the recess *x* cut in the upper edge of the barrel. In this position the sliders are depressed, so that the notch *r* made in each slider comes exactly opposite the steel ring *b b*, and the barrel is at liberty to turn round all the sliders, being by this means removed, or at least relieved from the steel ring, which, as before mentioned, embraces a groove cut round the barrel, but which cannot turn round therein unless the sliders are also moved by the key, so that the notches cut in them coincide with the groove cut round the barrel, and then it can turn freely round. The key, having thus relieved the barrel by being thrust in as far as it can go, obtains a hold of the barrel to turn it round, by the leaf *t* entering the recess *x*, which it exactly fills up, so as to form a continuation of the circular top of the barrel; but as soon as the key is turned round with the barrel a small quantity, its leaf is caught beneath the circular cavity in the top of the box D, and thus the key is prevented from being thrown out by the spiral spring *w*, until it has been turned quite round, having locked or unlocked the bolt; then the leaf of the key coming opposite the enlarged part *z* of fig. 3, of the keyhole H, the spring throws the key out and raises all the sliders, that they may interlock with the steel plate *b b*, and prevent the barrel from turning, unless the key is again put in, (its leaf being opposite the aperture *z* of the keyhole,) and being thrust forwards as far as it will go, the barrel will turn round very easily; and when it has made a complete circuit, the lock is opened, and the key thrown out of the keyhole by the spring.

The security of this ingenious lock from being picked or opened by a false key, depends upon a circumstance not yet mentioned, which is, that the notches in the six sliders are so made, that every one requires to be depressed a different quantity to bring them all at once opposite the steel ring, in which position alone the barrel can be moved. For this reason the six notches in the key are all of different depths, corresponding to the positions of the notches in their respective sliders, and unless each notch in the key is of the proper depth the lock cannot be opened, for any one being too deep, that slider will not be pressed low enough to relieve the barrel, and will hold it fast, though all the others may be correct; on the other hand, any notch not being of sufficient depth, the slider it acts upon will be pressed too far, and in this case the notch in it, having passed by the steel ring, will lock the barrel as effectually as if it was not far enough. Thus this lock admits of an

immense number of combinations: first in the number of the sliders; secondly, the depth of the different notches in the key; and thirdly, the arrangement of these sliders. The combination of these three changes admits such an immense number of varieties of locks, that it never need happen that two locks should be made to open by the same key. Any of Mr. Bramah's locks may be arranged so as to require a new and different key in case the original one should be lost or stolen; for this purpose the lock must be opened, and the sliders taken out and changed into different grooves; a new key must now be made with the grooves of the same depth of the original key, but arranged in a different order, corresponding with the new arrangement of the sliders. The old key will not now open the lock.

To pick a lock of this kind is perhaps impossible; because though the sliders are exposed to the examination of any person, yet no information can be obtained of the depth of each of the sliders required to be depressed, for, unless they are altogether pressed down, the barrel cannot be turned in the least, and without turning it, no guess can be made by pressing any one slider of the depth at which the notch in it will be opposite the steel ring. Another great advantage of these locks is, that, from the circumstance before explained of the bolt having no action to turn the barrel, though the barrel has a great power to shoot the bolt, a strong lock may have but a very small key. For instance, the bolt of the lock in the plate, which is drawn its full size, is of great strength, while the key R is so small that it may always be carried suspended to the watch chain, and then it will not be in danger of being lost or mislaid, as one may happen to lose a key, and thus give opportunity for ill-disposed persons to make a false key from it, unknown to the owner.

(415.) *The puzzle or combination lock.*—This, which acts as a padlock, is another very ingenious contrivance; which is represented in fig. 7, 8, according to the construction of which no key is required to open it, but only a particular combination of letters, whence the denomination of combination lock; and the difficulty of an indifferent person hitting upon the right combination out of the immense number which may be found, has given to it also the name of the puzzle lock; it is, perhaps, known equally well by either term.

Fig. 7 shows the instrument in an unlocked position, the staple A being upon its centre of motion. The lock consists of a number of circular rings of metal placed side by side upon a tube of the same diameter as the inside of the rings, so that all and each can turn round quite freely and independent of each other. Fig. 8 shows the details of the lock on a larger scale, only one of the rings being drawn to make it more clearly understood. B B is the tube on which the rings turn, soldered or otherwise firmly fixed by one of its ends to the end plate C of the lock, which also carries the centre pin *a* of the staple A. The tube B has a groove *l, l* made in its sides for the studs *2, 2* to move in, which studs project from a round bolt E, sliding endways within the tube B; the end *e* of the bolt is formed into a screw, which enters a hole in the end of the plate D, fig. 7, and unites them firmly together. The rings have each a notch in them, as at *3*, of sufficient size for the studs *2* to move in them, placed in a determined position; the staple A is prevented from being lifted up when the lock is fast by the circular pin *b* entering a hole in the end plate D; but if all the rings are turned

Machinery.

Combination or puzzle lock. Pl. xxxii. Fig. 7, 8.

Manufac-
tures.

round to one determined situation, their notches 3 all coincide so as to allow the studs 2, 2 to enter them. which is done by pulling the end plate D out, its bolt E, with its studs, will move endways clear of the pin b, and permit the staple A to be raised up, as in fig. 7; two marks *m m* are made on the edges of the end plates C D, and the letters on the circumference of the rings are brought for a particular word in a line between the said marks, as shown in fig. 7, where the letters form the word lock, when the notches 3 are in a line, and the end plate D can be withdrawn sufficiently to relieve the staple. We will now explain how the word can be altered at the pleasure of the owner. When the lock is in the position fig. 7, turn the plate D round, and it will unscrew from the bolt E, and the rings may be slipped off endways, one by one, by bringing their notches 3 over the studs 2; each of the rings is formed out of two concentric rings 5 and 6, fig. 8, the outer one, 5, having the letters of the alphabet imprinted on its circumference; it has also a number of small notches cut in its inner circle, corresponding in place with the letters on the outside; the inner ring 6, which slides upon the tube B, has a small projection from its outside, which enters any one of the notches in the outer ring; it has also a large notch 3 cut from the inside to allow the studs 2 to pass, and is turned out larger at the back side round the centre, for the studs to turn round in when the lock is fastened.

By this arrangement, whatever letter on the outside of the ring 5 is placed to correspond with the notch 3 in the inner ring 6, must also be placed in a line with the marks *m m*, fig. 7, to enable the lock to be opened; for if any one of the rings is not placed with the proper letter opposite the marks, the corresponding stud 2 will not enter its notch 3, and, consequently, the bolt E cannot be withdrawn so as to relieve the staple A.

The different combinations that a lock of the above description will admit of are immense; since each of the rings admit of twenty-four positions with respect to the notch 3 only. The owner of such a lock must be careful not to forget the opening word he last placed it at, as in such case it would require to be broken open by force, since there is no means of discovering the word except when the lock is open.

We cannot pursue this subject to a great length, but must refer the reader who wishes to learn more of the nature of these ingenious constructions to the volumes above quoted.

Bentham's
planing
Machine.

(416.) *Planing Machine for wood.*—After the operation of sawing there is no process more laborious, or on which more time is consumed by carpenters, millwrights, wheelwrights, and other workers in wood, than that of planing; and, accordingly, attempts have at different times been made to perform this mechanical process, in which little skill is required, by Machinery. The first attempt, we believe, was made by General Bentham, who, in 1791, took out a patent for a method of effecting this object, but notwithstanding the ingenuity of the inventor, it was not attended with all the advantages he had anticipated; indeed, the principal object of this patent was to exonerate the workman, not from the labour, but from the charge he had of his tool in the operation of planing, by so adjusting the cutting iron that it could not but perform the operation intended without requiring any of the skill of the workman, and thereby rendering a common labourer as serviceable as the best joiner for this purpose.

VOL. VII.

With this view the plane was made the full width of the board, and on each side of it were fixed fillets which projected below the face of the plane, just as much as it was intended to reduce the board in thickness, serving thereby to guide the plane sideways, and to gauge the thickness; because when the boards are reduced to this amount, the fillets will rest on the bench or which the boards are placed, and will no longer apply its edge to the plane. The plane was kept down by its own or by additional weights when necessary, which latter were so contrived as to be capable of having their position shifted during the time it was making the stroke, the pressure at first acting forwards, and lastly on the hinder part to prevent the fore end dipping down the instant it leaves the board. By another contrivance the plane was lifted up on its return, so as to clear the cutting edge from the wood. This was effected by a piece of wood which acted as a handle to the plane, and to which the power was applied: it was placed with this view upon an axle extending across the width of the plane, and carrying on each side a short lever provided with rollers at their extremities; the handle projected upwards from the plane, which being forced forward by it, assumed an inclined position, as also did the short levers, so that their rollers then rose above the cheeks of the plane; but when the latter was drawn back into an erect position, the levers moving with it, their rollers projected beneath the cheeks of the plane, and raised it off the bench, the plane being supported by them on its return.

The bench for supporting the board during the operation had also a peculiarity in its construction which it may be proper to describe. In cases where the boards to be planed were winding and irregular on the lower side, so that they could not lie flat upon the bench, it was provided with two cheeks which might be brought close to the edges of the board, so as to hold the latter steadily between them, the cheeks having been furnished with two or more rows of flat teeth to penetrate the wood, and to retain it in its place. These sides were so contrived as to rise and fall with the bench to accommodate the whole to different thicknesses of board. If a very thin board had to be planed, it would, of course, be liable to spring up to the iron, so as to be reduced after the plane came to rest with its cheeks upon the bench; to avoid this the edges of the board were held by the sides of the bench above mentioned, but as it would still be liable to spring up on its middle part, heavy rollers, or rollers loaded with weights, were fitted in apertures made in the plane, as near as possible to the cutting edge, which answered the intended purpose of keeping the plane down close to the bench. For planing pieces of greater thickness at one end than at the other, the cheeks of the plane were supported upon wooden rollers laid on the bench on each side the wood, as much thicker at one end as the board at the other; therefore, when the plane had reduced the wood, the cheeks came to their bearing on these rollers, and caused it to move, not parallel to the bench, but inclined according to the degree in which it was thicker at one end than at the other. In like manner, by using them of different thicknesses at the different sides, the boards might be made feather-edged.

This Machine might have been put in motion by Machinery, but we believe it never was worked usefully but by hand. In either case, however, as all the adjustments were made and regulated by the Machinery, none of the skill of the workman was required in the process.

2 T

Manufac-
tures.

Bramah's
planing
Machine.

(417.) The next great improvement in planing Machines was made by Mr. J. Bramah of Pimlico, who, in 1802, took out a patent for Machinery, for the purpose of producing straight, smooth, parallel surfaces, and curvilinear surfaces on wood and other materials requiring accuracy, in a manner much more expeditious than can be performed by the use of axes, saws, planes, and other cutting instruments used *by hand*. The description of this Machinery is very explicit, although not very elegant, as given in the specification; we shall, however, give it in the author's words, as reported in vol. ii. of the new series of the *Repertory of Arts*.

"The principal parts of my invention are as follows: that is to say, to shorten and reduce manual labour, and the consequent expenses which attend it, by producing the effects stated in my patent by the use of Machinery, which may be worked by animal, elementary, or manual force; and which said effects are to produce straight, true, smooth, and parallel surfaces in the preparation of all the component parts of work, consisting of wood, ivory, horn, stone, metals, or any other sort of materials or composition usually prepared, and render them true and fit for use by means of edge tools of every description. I do not rest the merits of this my said invention on any novelty in the general principle of the Machinery I employ, because the public benefit I propose will rather depend on new effects, produced by a new application of principles already known, and Machinery already in use for other purposes in various branches of British Manufacture. This Machinery, and the new manner of using it, with some improvements in the construction, together with sundry tools and appendages never in use before, are particularly described and explained here under.

"I mean to use and apply for the purposes above stated, every kind of edge tool or cutter already known, either in their present shape, or with such variations and improvements as the variety of operations I may encounter may severally call for. But the tools, instead of being applied by hand, as usual, I fix, as judgment may direct, on frames driven by Machinery, some of which frames I move in a rotary direction round an upright shaft, and others having their shaft lying in a horizontal position, like a common lathe for turning wood, &c. In other instances I fix these tools, cutters, &c., on frames which slide in stationed grooves or otherwise, and, like the former, calculated for connection with, and to be driven by Machinery, all of which are hereafter further explained and particularized.

"The principal points on which the merits of the invention rest are the following. First, I cause the materials meant to be wrought true and perfect as above described, to slide into contact with the tool, instead of the tool being carried by the hand over the work, in the usual way.

Secondly, I make the tool, of whatsoever cutting kind it be, to traverse across the work in a square or oblique direction, except in some cases where it may be necessary to fix the tool or cutter in an immovable station, and cause the work to fall in contact with it by a motion, confining it so to do, similar to the operations performed on a drawing bench.

"Thirdly, in some cases I use, instead of common saws, axes, planes, chisels, and other such instruments usually applied by hand, cutters, knives, shaves, planes, and the like, variously, as the nature of the work may render necessary; some in form of bent knives, spoke shaves, or deep cutting gauges, similar to those used by

turners for cutting off the roughest part. I also apply Machinery. planes of various shapes and construction, as the work may require, to follow the former in succession, under the same operation; and which latter I call finishers.

"Fourthly, these cutters, knives, &c., I fix on frames of wood or metal properly contrived for their reception, and from which they may be easily detached for the purpose of sharpening and the like: these I call cutter frames. These cutter frames I move in cases like those on which the saws are fixed in a sawing mill, and sometimes to reciprocate in a horizontal direction, confined and stationed by grooves or otherwise, as may be found best calculated to answer the several works intended. In other instances, and which, I apprehend, will generally have the preference, I fix cutter frames on a rotary upright shaft, turning on a step, and carrying the frame round in a direction similar to the upper millstone; and sometimes I cause the frames to turn on a horizontal shaft, just resembling the mandrel of a common turning lathe, or those Machines used for cutting logwood, &c., for the dyer's uses. When these frames are mounted in any of the foregoing directions for cutting, planes, &c., are fixed so as to fall successively in contact with the wood or other materials to be cut, so that the cutter or tool calculated to take the rough and hilly part operates the first, and those that follow must be so regulated as to reduce the material down to the line intended for the surface. These cutter frames must also have the property of being regulated by a screw or otherwise, so as to approach nearer the work, or recede at pleasure, in order that a deeper or shallower cut may be taken at discretion, or that the Machine may repeat its action without raising or depressing the materials on which they act. The manner of thus regulating the cutter frames, when on an upright shaft, is particularly described below. These cutter frames may be made of any magnitude and dimensions the work requires, only observing to make the diameter of those on the rotary plane so as to exceed twice the width of the materials to be cut, as the said materials must slide so as to pass the shaft on which the cutter frames revolve, when on the upright principle.

"Fifthly, When I use upright shafts for the purpose of carrying the cutter frame as above described, I do not mean that the lower end or point of such shafts shall come in contact with, or rest on, the bottom of the step or box in which they stand; neither do I mean that such said shafts shall rest or turn on any stationed unaltered point at rest, but the pivot or lower point of the shaft shall actually rest and turn on a fluid body, such as oil, or any other fluid proper for that purpose, a considerable portion of which is always to be kept between the lower point of the shaft and the bottom of the step in which it works. The said shafts may be either raised or depressed at pleasure to any required altitude, by means of a greater or less quantity of the said fluid being confined, as aforesaid, between the end of the shaft and the bottom of the step. This device I deem of great consequence in the fabrication of all kinds of Machinery, where massy and heavy loaded upright shafts are used; and I perform it in the following manner; that is to say, the lower part of the shaft must be turned perfectly smooth and cylindrical, to a height something above the greatest distance or length the shaft will ever be required to be raised or depressed when in use. This part of the shaft I immerse or drop into a hollow cylinder, which fits its circumference near enough to allow free

Manufac-
tures.

dom of motion, but sufficiently fitted to prevent shake. This cylinder I call the step cylinder, which must be of a length nearly equal to that of the cylindrical part of the shaft above mentioned, so that when the point of the shaft rests upon the bottom of the cylinder, the parallel or cylindrical part may be something above the top or upper end of the step cylinder. In the upper end of this step cylinder I make a stuffing box, by means of a double cupped leather or other materials surrounding the cylindrical part of the shaft, in such a way as will cause the junction, when the shaft is passed through it, to remain water tight under any pressure that may be felt from the efforts of the fluid, retained as above mentioned, to make its escape upwards through this part which I have called the stuffing box, when the shaft with all its load is passed through it, and immersed in the cylinder below. When this is done, the injection pipe of a small forcing pump, similar to those I use in my patent Press, must form a junction with the step cylinder in some part below the stuffing box; then the pump being worked, the oil or other fluid injected by it will, by pressing in all directions, cause the shaft to be raised from the rest on the bottom of the cylinder, and to be slid up through the stuffing box just the same as the piston of my patent Press; and by this means the shaft with all its incumbrance, and whatever may be its weight, may be raised to any given point at pleasure, and at the same time it will be left resting on the fluid under it, whatever the quantity or thickness of such fluid may be between its points and the bottom of the step cylinder. By this means the shaft, with all its incumbent load as aforesaid, should it even amount to hundreds or thousands of tons, can be easily raised and depressed to any required point at pleasure, by the alternate injection or discharge of the fluid used, exactly the same as performed by my Patent press as aforesaid; and at the same time all friction will be avoided, except that of the stuffing box, which will be comparatively trifling to that which would result from the resting of such a shaft on the bottom of the step in the usual way. Thus will be gained the properties above stated; and in addition thereto I think it may be inferred, that provided the stuffing box is kept perfectly fluid tight, such a shaft thus buoyed up by and turning in a proper fluid, may continue working for years, or perhaps hundreds of years, without a fresh supply of oil, or whatever other fluid substance is found the most proper to apply.

"Sixthly, the material that is to be cut and made true must be firmly fixed on a platform or frame, made to slide with perfect truth, either on wheels or in grooves, &c., similar to those frames in a saw-mill, on which the timber is carried to the saws. These frames must be moved in a steady, progressive manner, as the cutter frame turns round either by the same power which moves the latter, or otherwise as may be found to answer best in practice. This motion also must be under the power of a regulator; so that the motion of the sliding frame may be properly adjusted according to the nature of the work. The motion of the cutter frames must also be under the control of a regulator; so that the velocity of the tool in passing over the work may be made quicker or slower, as such work may respectively require, to cause the cutter to act properly and to the best advantage.

"Seventhly, I regulate the motions of both these parts of the apparatus as aforementioned, by means of a new invention, which I call a universal regulator of velocity,

and which is composed as follows; viz. I take any number of cog wheels, of different diameters, with teeth, that will exactly fit each other through the whole, suppose ten or any other number, but for example say ten, the smallest of which shall not exceed one inch in diameter, and the largest, suppose ten inches in diameter, and all the rest to mount by regular gradations in their diameters from one to ten. I fix these ten wheels fast and immovable, on an axis perfectly true, so as to form a cone of wheels. I then take ten other wheels, exactly the same in all respects as the former, and fix them on another axis also, perfectly true, and the wheels in conical gradation also; but these latter wheels I do not fix fast on their axis, like the former, but leave them all loose so as to turn upon the said axis, contrary to the former which are fixed. All these latter wheels I have the power of locking by a pin, or otherwise, so that I can at discretion lock or set fast any single wheel at pleasure. I then place the two axes parallel to each other, with the wheels which form the two cones, as above described, in reverse position, so that the large wheel at the one end of the cone may lock its teeth into the smallest one in the cone opposite, and likewise *vice versa*. Then suppose the axis on which the wheels are permanently fixed to be turned about, all the wheels on the other axis will be carried round with an equal velocity with the former, but their axis will not move. Then lock the longest wheel on the loose axis, and by turning about the fastened axis as before, it must make ten revolutions while the opposite perform but one; then by unlocking the longest wheel and locking the smallest one at the contrary end of the cone in its stead, and turning as before, the fastened axis will then turn the opposite ten times, while itself only revolves once. Thus the axes or shafts of these cones, or conical combination of wheels, may turn each other reciprocally, as one to ten, and as ten to one, which collectively produces a change in velocity under a uniform action of the *primum mobile*, as ten to a hundred: for when the small wheel on the loose axis is locked, and the fast one makes ten revolutions, the former will have one hundred. And by adding to the number of these wheels and extending the cones, which may be done *ad infinitum*, velocity may be likewise infinitely varied by this simple contrivance: A may turn B with a speed equal to thousands or millions of times its own motion; and by changing a pin and locking a different wheel, as above described, B will turn A in the same proportion, and their power be *transferred to each, in a proportion reciprocally as their velocities*. Here is, then, a universal regulator at once for both power and velocity. In some instances I produce a like effect by the same necessary number of wheels, made to correspond in conical order, but instead of being all constantly mounted on the axes or shafts, as above described, they will reciprocally be changed from one axis to the other in single pairs, matched according to the speed or power wanted, just as in the former instance. This method will have in all respects the same effect, but is not so convenient as when the wheels are all fixed, &c.

"Eighthly, when spherical surfaces are to be produced perfectly true, and equidistant from their centres in all directions, I use a tool or cutter, of a proper shape, according to the nature of the materials to be cut. This tool must be fixed on a cutter frame, fastened to the rest of any common lathe, so as to present its point exactly to a line drawn through the centre of the man-

Machinery

Manufac-
tures.

drel of the lathe horizontally, and the said frame on which the cutter is fixed must have the capacity of drawing out, at pleasure, to any required distance, to accommodate the diameter of the sphere to be cut or turned true. This cutter frame must be likewise made to turn upon a centre or pin, very firm and steadily fixed on the rest above mentioned, so as to enable the cutter to be turned by its frame round a centre exactly perpendicular to the centre of the lathe or line before mentioned, by which the altitude of the tool's point is to be regulated; when this is done, and the wood or other material is fixed on the lathe in the usual way, the cutter frame must be drawn nearer or further distant from the centre on which it turns, to accommodate the diameter, just the same as the common rest. If the materials be rough, and require to be reduced to a spherical form by gradations, the work may be repeatedly gone over by the cutter before it reaches the diameter proposed. By this simple apparatus the difficulty of turning perfect spheres is overcome; as it must be obvious to any person of the most ordinary capacity in Mechanics, that while the work is turning in the lathe in a vertical direction, and the tool or cutter is by the hand or otherwise turned at the same time, in a perfectly horizontal direction round a centre, opposite to the actual centre of the sphere, the point of the tool or cutter must, of necessity, generate or turn a perfect sphere, true in all directions, without the smallest attention or assistance from the use of the instrument. I mention here the application of the cutter frame to a common lathe, conceiving it will, by such an explanation, be more familiarly understood without a drawing; but, by this method, spheres of any practical magnitude may be cut with perfect ease and certainty.

"Ninthly, when concave surfaces are to be produced perfectly true, smooth, and equidistant from their respective spherical centres, the work is fixed on a Machine, the same in all respects as the common turning lathe, as in the instance last referred to; I then fix a tool or cutter on a centre, exactly in a line, both perpendicular to and on a level with the exact centre of the shaft or mandrel on which the work revolves: and which cutter or tool projects to the required radial distance with its point, so that when the work goes round by the revolution of the lathe, the tool or cutter at the same time revolving round its centre, a spherical concave will be generated and produced by the fluxion of its point, as in the instance of the convex sphere.

"Tenthly, I convert solid wood, or other materials, into a thin concave shell, similar to a dish; I cut them alternately out of each other, beginning at the smallest, by means of another tool or cutter, likewise moving on a stationed centre as before, exactly on a level with and perpendicularly true with the centre of the mandrel or shaft of the Machine on which the work is fixed. This tool or cutter is made at its exterior point or cutting end of such a shape as best suits the nature of the work; and its shank or stem is bent to the exact circle the concave is meant to be: it is then fixed on an arm or frame calculated to receive others of different circles according to the work; in fact, the same frame may be used which is above described to hold the tool for cutting spheres, either of the concave or convex kind. The tool must be fixed on this frame or arm, as above mentioned, at such a radial distance from the centre on which the frame or arm turns, so as to form a quadrant, with one leg turning on its centre and the tool forming

the periphery with its cutting point projecting to the line of the deficient leg. Before this tool begins its action, a common rest must be applied close to the face of the work, in order to support the tool when it begins its cut, and on which rest the tool will slide till its point proceeds under the control of the centre on which its frame is fixed, until it reaches the horizontal line of the lathe's centre, when the part cut off, or the inner dish, will fall from the stock, and leave the rest for the operation of another tool of a larger circle. Thus the operation may be repeated till the whole lump is converted according to the intentions of the owner."

(418.) *Planing Machine in the Royal Arsenal, Woolwich.*—According to views laid down in the above specification, Mr. Bramah constructed the Machine employed in his own workshop, but that which we are about to describe being a subsequent construction, differs in many essential parts from the former, and is perhaps as perfect as such a Machine can be made. In the carriage department of the Royal Arsenal, where all the gun carriages, both for the artillery and for the marine, are constructed, there is a great deal of very heavy planing, and if in any establishment such a Machine can be advantageously employed, it is in this. The Machine is represented in plate xxxiii., where fig. 1 and 2 show the elevation and plan, and the other figures such parts as require particular description.

Referring to fig. 1, *a a* is a solid bed of brick and stonework, intended to form a foundation for the Machine, and rising one foot above the ground-floor; *b b* are iron slides fixed firmly to the foundation stones, shown in fig. 2, and inclining half an inch from the horizontal line in the whole length (forty feet) towards *B*; *c c*, *d d*, are the movable carriages, on which the wood *e e*, intended to be planed, is supported; *f f* is the cylinder of an hydraulic or hydrostatic Press, having two entrance pipes *g* and *h*, one at each extremity. The piston rod of this Press is furnished with a rack *i i*, which works a pinion *j*, under and attached to the wheel *w*. Round this wheel and the three smaller wheels *W W W* passes an endless chain, which may be stretched at pleasure, so as to keep it to its work by means of a screw attached to the movable slider carrying the centre wheel. The cylinder containing the condensed or compressed water is in an adjacent room, and therefore not shown in the drawing; the water is, however, conveyed by pipes to the cocks at *k*, which are so contrived as to admit of the compressed fluid being directed through the pipes *g* or *h*, and such that, when the pipe *g*, for example, is opened to the compression, the pipe *h* is made to communicate with the waste; hence when the water enters at *g*, the piston is urged forwards, and the rack working on the pinion, under the wheel *w*, gives motion to the chain and to the carriages attached to it. This brings the carriages *c c* from the extremity *A* towards *B*, and at the same time, the carriage *d d* towards *A*, at least when this latter is also attached to the chain, but generally only one carriage is attached at a time. The carriage *c c* having been advanced as far as requisite towards *B*, the cock at *k* is turned, the pipe *g* is opened to the waste water, and the pipe *h* to the compression, the carriage then turns towards *A*, when the pipe *h* opens to the water and the pipe *g* to compression, and the carriage again returns.

The means employed to give motion to the carriage being thus explained, we must now endeavour to illustrate the operation of the planing wheel. In the eleva-

tures.

tion fig. 1, C C is a strong vertical iron spindle, carrying the horizontal iron wheel H H, which in its circumference or rim is pierced with thirty holes, furnished with twenty-eight gouges or cutters and two planes. This wheel, which is preserved horizontally by twelve braces, *m l, m l*, is put in rotation by the wheelwork shown in the figure, at the rate of about ninety revolutions per minute, F F being the principal shaft or axle connected with a steam engine in an adjacent apartment. D D, fig. 1, are the sections of two principal beams across the workshop; E E, E E, two uprights, or pillars, which with the woodwork shown above, and two other pillars not shown, serve to give stability to the Machine, and to support the stout wire guard *n n n n*, intended to protect bystanders from accident, to which they might be otherwise exposed.

In the general character of this Machine, its operation is pretty obvious; while the carriages are passing from one end of the slider to the other, by the action of the hydraulic Press above explained, the wheel is put in rotation, and so adjusted by means of another hydraulic Press, that the gouges and planers attached to the horizontal wheel H H just catch the surface of the piece of wood *e e* in its passage under it. The gouges being arranged in its rim, at different distances from the centre, and these being followed by the two planing irons in the rotation, render the surface thus exposed to the operation beautifully plane and smooth.

It is stated above, that not only the carriages are passed backwards and forwards under the cutter by means of hydraulic pressure, but also that the wheel itself is sustained and adjusted by the same means. The general principle of this action may be sufficiently understood from the figures in the plate referred to, but the apparatus for changing the direction of the motion being very small on the scale of the drawing, may require a few words of additional illustration. This is effected by what is called a four-way cock, shown on a larger scale in fig. 3. Here A B D C represent the part shown at fig. 1 and fig. 2; *h* is an opening into the pipe leading to the end *h* of the cylinder or hydraulic press, and *g* is another pipe leading to the end *g* of the same cylinder; *a* is an opening into the pipe leading to the vessel in which the compressed air and water is contained, and *b* an opening into the pipe leading to the waste or open atmosphere, and therefore only exposed to the pressure of the latter, whereas the water in the pipe sustains a pressure of fourteen hundred pounds per square inch. P is a circular plug having within it two curved ways, which may be made to unite at pleasure either *h* with *b*, and *g* with *a*, as represented in the figure, or by turning a quarter round they will unite *h* with *a*, and *g* with *b*. In the former case the piston will be urged from *g* towards *h*, fig. 2, and in the latter from *h* towards *g*. The motion of this plug is under the control of the workman superintending, by means of the handle shown at *k*. To effect this change, a motion amounting to a quadrant or 90° is necessary, but if a motion of the handle is made of only half a quadrant, then the ways are all shut and the Machine remains stationary.

The method of raising the cutting wheel and spindle is as nearly as possible the same, except that here it is only necessary to connect alternately the bottom of the vertical cylinder with the charge pipe and waste; therefore in this case the central plug has but one curved way, which may be turned so as to connect the bottom of the cylinder with the charge pipe when the wheel and

cutters are to be raised, or with the waste when it is to be lowered, or it may be placed intermediately between the two positions, preserving the wheel stationary as during the time the timber is under the planing operation. Fig. 4 shows the method of fixing the timber to the carriages.

(419.) *Machine for planing iron.*—Formerly, when the construction of Machines was less common, and their action less accurate than at present, the only method of obtaining a level metallic face on iron, was by first chipping it with a cold chisel to a tolerably level plane, and then completing the operation by the file; but since the extraordinary employment of Machinery in this Country, that process has been found too slow for the rapidity with which Machines have been required, and too uncertain and imperfect for the due execution of the operations they have been intended to perform. Accordingly many attempts have been made to supersede the above laborious manual process by the substitution of Machinery, and different methods of effecting this desirable object have been proposed. In some of these the cutters intended to form the surface have been made to revolve, while the plate whose surface was to be formed moved slowly under them, something after the manner of the wood planing Machine last described. Generally, however, the motion has been rectilinear; in one case the cutter or plane having been made to pass over the body on which the operation is to be performed, and in others the plane has remained stationary while the body passed beneath.

The latter is now most commonly adopted. At Messrs. Sharp and Roberts's manufactory at Manchester, there are several such Machines, one of which, on a very large scale, is perhaps the most perfect in the Kingdom. When we saw it at work, it was planing the face of a large lathe bed, of fifteen feet length, and with a face of ten inches. The work was nearly completed, and nothing could exceed the beautiful surface that had been obtained.

The planing tool is fixed in a frame supported by a strong upright cast iron frame, the former being adjustable both laterally and vertically to bring it to its work; it may also be inclined at any angle to enable it to plane any inclined surface, and being accurately graduated, the required bevel is immediately set on without difficulty or loss of time. The frame also has a motion whereby at the end of the stroke it rises and allows the carriage bearing the body to be planed to pass back free of the cutter. In this way the largest surfaces are planed by the assistance of a single workman to adjust the cutter after every stroke; but even the amount of this motion is so much under the dominion of the Machine itself, that it is nearly impossible for him to commit any error. The apparent ease with which shaving after shaving is stripped away, is to a person not accustomed to witness such operations truly wonderful, and never fails to excite their surprise.

Besides this large planing Machine, there are several smaller ones in the same establishment, whereby the use of the chisel and file is almost wholly superseded.

The above Machines are obviously only calculated for heavy strong work; in more delicate operations, whether for planing wood or metal, a Machine has been invented and constructed by Mr. Clements, which is considered to be a very perfect piece of workmanship, and we are sorry that the number of figures requisite for its full illustration is so great that we are under the necessity of passing it over without description. We can

General
remarks on
the nature
of pressure.

only refer the reader, who is desirous of being thoroughly informed respecting its mechanism, to the *Transactions of the Society of Arts*, part i. vol xlix.

(420.) *Of Presses and Machines acting by pressure.*—As presses assume a great variety of forms in different mechanical processes, and as these are commonly better described in connection with the Machine or process in which they occur, we shall only take in this place a general view of the nature of pressure, and the description of one or two Presses not elsewhere noticed, and for the rest shall merely refer to those articles where any particular application has been already explained. The objects attained by pressure are to compress bodies into small space, as in the Packing Press; to augment their dimensions in a particular direction, as in the Rolling Presses, or Rolling Mills for iron, lead, copper, &c.; to divide the substance of bodies, either wholly or partially, as in cutting the blanks, and afterwards impressing certain figures, as in coining; to reduce them to more minute portions, as in stamping ores and similar processes. The Machines by which these several operations are effected may be considered as different descriptions of Presses; but custom has limited the term Press only to some of them, and generally to those which act by means of a screw, and to the Hydraulic Press invented by Mr. Bramah.

The screw of the Press is generally turned by a lever, for without this assistance, however powerful the Press might be, the friction of the screw, which is always very great, would render it almost useless; but this friction being once overcome, it is found of great convenience, being generally sufficient to furnish its own pail, or to prevent any retrograding, retaining thus the pressure acquired without the necessity of any other mechanical means. When great force is required, the screw, that is, the threads are made as close as possible consistent with their strength; but in such cases a double screw, hereafter described, may be advantageously employed. The screw of a Printing Press or of a Stamping Press is, on the contrary, very open, and it is caused to descend with considerable velocity and momentum, the handle being loaded with a weight for that purpose. Wherever a force is so employed as to produce an impulse which acts on any body, the momentum, which is the result of the action of the force for a certain time, is usually much more powerful than the simple pressure; but the degree of its efficacy depends on the degree of compressibility of its substance. If a heavy body fall from a certain height, so as to acquire a momentum, in consequence of the force of Gravity, it will ultimately exert upon the substance on which it falls a force about as much greater than its weight, as the space through which the substance struck is depressed, by means of the impulse, is less than twice the height from which the body has fallen, and unless the body is very compressible, or the height very small, this force must be incomparably greater than the pressure of the weight only: and in this way we must account for the effect of the Presses used in coining, in button making, and other such processes. See those articles.

In a Printing Press it will be seen that a single heavy roller is sometimes made to pass over the paper, when it has been laid on the types, and since the whole action of such a roller is confined to a small part at any one time, it is found to exert sufficient force, and to perform its work more accurately than the old common Printing Press. The Mangle for domestic purposes, although

not commonly thus classed, is amongst the latter description of Presses, and so also, indeed, is the cylindrical and common Calender, the Copper-plate Press, and the Copying Press. Again, the Sugar-mill, although not commonly spoken of under the denomination of a Press, is, in fact, a Machine of this class, the pressure being exerted between the rollers as the cane passes through; so also the Rolling Mills for lead, iron, and other metals; (see those articles;) and even wiredrawing is, by Dr. Young, included in this class of operations, the force originally employed in the direction of extension being much less than the lateral compression brought on by means of the conical apertures through which the wire is successively drawn.

Of these different Presses and forms of pressure, we shall here, however, confine our description to such only as are, in the common language of the Arts, known under the name of Presses, and of those only, to such as are not elsewhere described in this Work.

(421.) *Common screw packing Press.*—All these are of nearly the same kind, having generally a single screw, formed either of wood or iron, which at its lower end has an enlarged head, with holes through it for the reception of the end of the lever employed to turn the screw, the thread of which is fitted through a nut fixed fast in the head of the wood or iron frame of the Press. The frame consists of a lower bed or horizontal piece, on which the goods to be packed, or the matters to be compressed, are laid, two upright cheeks being firmly united with it, and supporting the head or upper horizontal piece of the Press in which the nut of the screw is fixed; the lower point of the screw is united with the follower or moving bed of the Press, and this rests upon the substance to be pressed, while the power of the screw forces it down upon it, and where it is retained after every effort by the natural friction of the screw as above stated. See fig. 1, plate xxxiv. The screws for Presses were formerly made of wood with sharp threads, that is, the worm of the screw, if cut across, would make a triangular section, the base abutting against the cylinder of the screw; but in this way it was necessary to have threads very coarse to give them sufficient strength, and, consequently, the power of the screw was not so great as in modern Presses, where the screw is formed of iron, as their threads need not be one-third the thickness of those of wooden screws; the latter are, however, still used where great strength is not required.

We have said that commonly the Screw Press consists of one screw and two fixed cheeks; but there is another kind of Press in which two screws are immovably fixed in the lower board or bed, and passing through holes in the upper board have nuts upon them, which being turned by a lever draw the two boards together and exert a pressure upon any thing placed between them. These screws sometimes pass through the upper board and are tapped into the lower one; in which case the screws themselves are turned round by a lever put through their heads instead of turning the nuts. Presses of this kind, when accurately made, have a communication of wheelwork from one screw to the other, so that both may turn accurately together, and cause the two boards of the Press to advance parallel to each other.

In 1797, Mr. John Pack obtained a reward from the Society of Arts for a very ingenious Packing Press of this kind. This Machine consists of two very strong horizontal beams at the top and bottom of the Press. These are united by two iron screws, which stand in a

Machinery.

Packing
Press with
double
screw.

Manufac-
tures.

vertical position, and, therefore, serve as cheeks to the Press. The follower of this Press is a very strong horizontal beam, having two nuts fitted into it at its ends. These nuts act upon the threads of the two vertical screws; and, therefore, it is plain when they are turned round, the follower will rise and fall upon them. The nuts are so fitted into the follower as to admit of a circular motion round the screws, but are not permitted to rise or fall without the follower, because they have a circular ring or projection in the middle of their length, which is fitted into proper receptacles in the woodwork. To give them motion, the edges of the circular rings are cut into cogs or teeth, and are turned by means of an endless screw for each, situated at the opposite ends of a horizontal spindle, which revolves in bearings attached to the follower of the Press. The spindle has a winch at each end, by turning which the two endless screws act upon the wheels or teeth of the nuts; and by thus causing them to turn round with equal velocities, raises or depresses the follower, always parallel to itself, and also to the head and bottom bed.

The great utility of this Press consists in its being capable of packing two sets of bales at once; thus answering the purpose of two Presses, and with more expedition. It is placed upon the floor of the warehouse in which the packing is to be performed, and behind it a stage is erected, just half the height of the whole Press; then one set of the bales are made up on the floor, and the other upon the stage. Suppose the follower raised up above the level of the stage, a bale of goods is placed on the lower bed, and by turning the winches, the follower is forced down upon it, till it is sufficiently pressed; now, while the men below are tying and making the bale fast, the people on the stage place a bale upon the follower; and it is plain that when the follower is raised up to relieve the lower package, the upper bale will be compressed between the follower and the head of the Press; and while this is making fast, the workmen below get another bale of goods loaded in. By this means no time is ever lost in screwing up or opening the Press; for it performs work both ways, which is a matter of no small importance in large works.

Press with
differential
screw.

(422.) In the *Philosophical Transactions* for 1781 is an account of a double screw, applied to a Press by Mr. W. Hunter. To explain this, we must suppose a single Screw Press of the ordinary form, but the lower end of the screw, which rests upon the follower or presser, has a second screw of finer thread cut upon it. This thread is received into a nut or barrel, which rests upon the presser. The nut is at liberty to turn round freely upon the presser, except when it is required to be stationary; and then by a key it can be fixed fast to it. In like manner, the nut or barrel can at pleasure be fixed fast to the lower screw by a key put through a hole in both; and in this state they will of course turn round together. As the nut and lower screw take up some room, the screw is turned by arms fixed in a head formed on the upper end of it above the Press. In the operation of this Press the nut or barrel is pinned fast to the lower screw by the key; and the screw being turned by the arms at top, the nut is carried round with it, and the effect is exactly the same as an ordinary Screw Press. But having by this means given as great a pressure as the single screw is capable of producing, the cross key which unites the lower screw to the barrel is removed, and is put in such a position, that it unites the barrel to the presser, so as to prevent its turning round upon it.

Machinery.

The effect of the Press now becomes compound, and while the whole screw is carried downwards by the revolution of the great screw, the fine screw at the bottom of it screws down into the barrel or nut, which is attached to the presser, which is therefore carried down a quantity only equal to the difference of the thread of the two screws; and if these are made very nearly alike, the descent produced by the difference between them will be exceedingly small, and the power exerted upon the articles under pressure will be in proportion to it. Indeed, the effect would be the same as if a single screw had been employed, having its threads so fine or close together, that the difference between thread and thread is only equal to the difference between the threads of the two screws.

For example, suppose it was required to produce a strong pressure, with a screw of ten threads in an inch, it is evident that the metallic protuberance, or helix of the screw, could not be quite so thick as one-twentieth of an inch, and could not, therefore, withstand any considerable force; but by the present construction, we may have the thread as strong as can be desired. Thus, if the slightest be a quarter of an inch, the finest screw must have two turns in the inch, and the coarsest two turns in one inch and one-tenth; or in other words, it would pass over the same space in ten turns that the other screw would in eleven.

These differential screws are extremely convenient in measuring small quantities, without requiring very fine screws. The finest screws usually to be met with do not exceed 100 threads in the inch, and few have been made finer than 200 in the same space. Let us consider by what threads of the usual or even coarse numbers we could have a difference per turn of 1000th of an inch, and we shall find that the difference between a thread of 32 and one of 33 in the inch is the 1056th part of an inch; so likewise the difference between a 60th and 61 parts of an inch is the 3660th part.

The writer has seen a delicate application of this principle by Mr. Barton, formerly of the Mint, who had two screws of 100 and 101 threads to the inch, which by their difference is equivalent to 10,100th part of an inch; but one being furnished with a micrometer head, which might be read to 100th, furnished the means of measuring a quantity of less than 1,000,000th of an inch.

(423.) *Hydraulic or Hydrostatic Press.*—The principle on which the Hydraulic Press is founded, which depends upon the equilibrium of pressure in fluids, was long known before the idea was suggested to apply it to mechanical purposes; and after the idea was advanced by Pascal, it was still more than a century before it was put in practice by Mr. Bramah, who took out a patent for the invention in 1791. Since this time the Hydraulic Press has gradually superseded the use of the Screw Press in most cases where great power is required; and, indeed, in all cases its application is more simple, its operation more expeditious, and the power almost unlimited, whether it be employed in the actual process of pressing, or in drawing or lifting great weights. Experiments have been made, in which piles, driven for the purpose of forming coffer dams, have been drawn by it with ease; even large trees have been drawn up with it by their roots, and iron bolts and cables, capable of holding the largest vessels in the British Navy, have been torn asunder with it in a few minutes. As it will be necessary to speak of the Machine in several of our descriptions, we shall in this place only explain its operation as a simple

Hydraulic
Packing
Press.

Manufac-
tures.

Pl. xxxiv.
Fig. 2, 3, 4, 5.

Press for packing, and describe the general principle of its action, and the mode of packing or leathering, leaving the more minute account of its operation to be particularized in the mechanical processes in which they occur.

(424.) A very simple form of packing Press of this kind, as it is constructed in several of our Government establishments, is shown in fig. 2, where F represents a short strong iron cylinder accurately bored and fitted with a solid plunger or piston rod D, both very accurately turned; this cylinder is sustained in the bottom cross bar of the Press, and sunk below the floor. A A are two strong iron sides, either cylindrical, or having any other figure at pleasure; a cross beam unites these uprights above by screws, and nuts or keys at *a a*, and an iron plate E is attached to the top of the piston rod, and guided in its motion by the uprights A A. L is the cistern of the forcing pump, and *b* a small pipe connecting the pump with the cylinder, which it enters as shown in the figure. And this constitutes the entire principle of the Press; for whatever pressure is exerted on the small area of the valve where the pipe enters the cylinder, that amount of pressure is multiplied in the Press as many times as the area of the plunger exceeds that of the valve. If, for example, the diameter of the valve were $\frac{1}{4}$ of an inch, and that of the plunger 6 inches, the area of the sections would be as $\frac{1}{16}$ to 36, or as 1 to 576; a pressure, therefore, of 10 pounds on the valve would produce a corresponding pressure on the press of 5760 pounds, or supposing the leverage of the pump to give a power of 10 to 1, then a pressure of 1 pound at H would balance a weight of 5760 pounds at E. Such is the simple principle of this powerful Machine; but where such great pressures are sustained, particular care and precautions are necessary to insure accuracy and to prevent leakage, which, as we shall not again touch upon the subject where we may have occasion to refer to this Machine, we propose to describe in this place; premising only that we have here only a single pump, whereas in the most powerful of these Machines there are three, four, or more pumps with double handles worked like a fire engine, and sometimes the cylinder of the Press is open at both ends, and the plunger or piston rod passes through both, the diameter at the upper end being much greater than at the lower, so that the area of pressure is the difference between the two sections. One advantage of such a construction is that the piston rod is thus guided in its direction without requiring aid in this respect from any external body; in this form also it is more convenient for bringing on a pulling instead of a pushing or pressing force. The pump does not differ essentially from another forcing pump; it is supplied with a valve below, commonly of the conical form to admit water from the cistern, when the plunger is raised, and another opening towards the pipe *b* to admit the water, when under the action of the plunger, into the pipe and cylinder; it is also supplied with a steel yard safety valve, and a screw cock for relieving the Press, and for returning the water into the cistern when the operation is completed, or at any other time. The safety valve is shown at *k*, and the relieving or the return cock at *i*.

Method of
leathering.

(425.) It now remains only to explain the means had recourse to for preventing leakage in the cylinder. For this purpose, the cylinder D is surrounded by a collar of leather at *o o*, fig. 3, the leather being formed as shown in fig. 4, the former figure representing the

upper end of the cylinder, and the latter the leather turned up to form a double cut, so that it resembles the cuff of a coat sleeve. When in its place it is kept distended by a copper ring, entering the circular channel or fold of the leather. This ring has a lodgement in a recess formed within the cylinder F. The leather is kept down by a brass or bell metal ring *m*, which is received into a recess formed round within the cylinder, as shown in fig. 3. The interior aperture of this ring is adapted to receive the cylinder D, and thus the leather becomes confined in a cell, with the edge of the interior fold applied to the cylinder D, whilst the edge of the outer fold is in contact with the interior surface of the cylinder F. In this situation the pressure of the water, acting between the folds of the leather, forces its edges into close contact with both, and makes a tight fitting round the cylinder, and as the pressure is increased, the leather is applied more closely, so as to prevent leakage under any circumstances. The metal ring *m* is truly turned in the lathe, and the cavity or cell formed for its reception; then to get it into its place, it is divided by a saw into five segments, as in fig. 5. Three of the lines at which it is divided point to the centre, but the other two are parallel to each other, and the ring is put into its place (after the leather and copper rings are introduced) by putting in the four segments separately, and the one with parallel sides is put in last. The cylinder D is then put down in its place, and ready for action. This plan of a divided ring was first used by the late Mr. Peter Kier, who, after the expiration of Mr. Bramah's patent, made several Hydrostatic Presses. In the original construction, the ring or head of the cylinder, which kept down the leather cup, was held down in its place by several screw bolts, but as these had to bear a greater force than the whole power of the Press, they were frequently torn out or strained, so as to cause leakage. The upper part of the cylinder above the ring *m* is filled with tow, or other kinds of packing, impregnated with sweet oil, which is confined by a thin plate or ring. This packing serves at once to supply the cylinder with oil, and to prevent the admission of any substance which might injure the surface of the piston.

(426.) The operation of this Press may be very readily comprehended, by supposing the pump, cylinder, and connecting pipe *b* to be filled with water, and that an adequate supply of water is contained in the cylinder L. When the handle of the lever H is raised, it brings up the piston rod *f*, which would leave a vacuum beneath, if the atmosphere did not force the water through the lower or suction valve of the pump. The lever being then pressed down, the piston rod, by descending, diminishes the capacity of the pump; this causes the lower valve to shut, and forces the water through the lower valve, whence it passes by the pipe *b* into the cavity of the great cylinder F, and raises the piston D and pressing table E, together with its load, a distance proportioned to the quantity of fluid injected. On the subsequent rise of the piston of the pump, the descent of the upper valve prevents the return of the water, and consequently the fall of the cylinder D. A repetition of the same process injects more water, and the pressure may, in this manner, be carried to a great extent. When it is proposed to relieve the action of the Press, the discharge valve *i* must be opened by turning the screw back; the water then escapes out of the Press into the cistern L, and consequently the table E and the

Power gained by the Press.

cylinder D, descend by their weight, restoring the engine to its original situation.

We have already pointed out the proportional power of the Hydraulic Press, supposing one pump only, but it has also been observed that there are frequently several pumps and several men employed, when of course the power is much greater; and in these cases there is commonly a convenience of shutting off one pump and then another as the pressures increase, so that at length the power of six or more men is thrown upon one pump only, and a pressure is obtained of perhaps two hundred tons or more; and the Presses in many cases are ensured to that amount. These, however, are not packing Presses, but such as we have described under the article Proving Machines for Iron Cables, and for such purposes. Mr. Farey, in making a comparison between a Press of this description and the common Screw Press observes, that a man in the act of pumping by a downwards pressure, can without difficulty apply his whole weight, and with great ease one-third or one-fourth of his weight, which we may take at a medium at 50 pounds. Supposing, then, the leverage of the pump, together with the ratio of the valve to an inch surface on the piston, to be as 1 to 120, every inch of the piston will sustain a pressure of 6000 pounds, or nearly three tons; and in comparing this with a Screw Press, he observes, we must first inquire what fineness of thread and length of lever would afford a purchase of 120 to 1. Let us suppose the thread of a screw, substituted in the place of the cylinder D, to be one-tenth of an inch thick, the distance from the top of one thread to the top of the next will in this case be one-fifth of an inch. This is the space through which the weight must rise in one revolution of the screw; the power must, therefore, move through 120 times that space, namely, twenty-four inches. A lever or radius four inches long will describe a circle somewhat longer than this, and consequently such an engine would, in theory, be equal in power to the Hydraulic Press we have been describing.

But when the subject is viewed practically, the difference between the two Machines appears to be very remarkable. All practical men know how very large a part of the force, operating by means of engines, is employed in overcoming friction; every one is aware of the extreme friction between solids, and the very slight friction which takes place between the parts of fluids. This is seen in the common expedient of oiling the pivots of the wheels, and in the very gradual decay of motion in fluid bodies, while solids moving upon each other stop at once as soon as the force is diminished to a certain degree. The screw is a power peculiarly liable to friction, and this friction is always much greater than the whole of the reacting force; for there are few instances where a screw will return from extreme pressure, when the agency upon the lever is withdrawn. It is also to be considered, that the whole force of the weight or resistance acts directly upon the face of the thread of the screw at the place where the motion is required to take place. It has not been ascertained in what degree this resistance or friction increases with its weight. In lighter actions the simple ratio has been inferred, but under more severe pressure, the two metallic faces exclude the greater part of the semifluid matter between them, and appear by the magnitude of their resistance to be attached to each other by cohesive attraction.

Mr. Nicholson, in his *Journal*, relates the following experiments, which he made with one of Mr. Bramah's

VOL. VII.

small Presses, which he makes for the purpose of copying letters or writings, in the manner of Mr. Watt; it had the same parts which we have described, but the frame made of wood. When employed to press papers, the force applied to the lever of the injection pump was so slight, that the instrument required no fastening to the table on which it stood; but the effect of the upper bar, which was of wood three inches and a half thick, was such, as bended it out of a straight line upwards of a quarter of an inch, and it appeared that it might have easily been broken by continuing the pressure. With a Screw Press, the screw of which was iron, and nearly of the dimensions above mentioned, excepting that the lever was twelve inches long instead of four inches, and the action on the lever upwards of two hundred weight, applied with a jerk, the effect was nearly the same; he estimated the advantage to be very much in favour of the Hydraulic Press.

In another Press of this kind, the diameter of the greater piston was four inches, and of the smaller three-eighths of an inch, and the advantage given by the lever or handle was twelve to one. Above the piston of the great cylinder was applied a long lever, at one end of which was an axis, and at the other end a large scale to hold weights; it contained twenty hundred weight. The distance between the axis of motion of this lever and the part where it acted on the piston was six inches; and the distance from the same axis to the extremity where the scale was hung was one hundred and twenty-six inches, every hundred weight in the scale consequently pressed upon the piston with a force equal to twenty-one hundred weight, whence the whole pressure was twenty-one tons. It was easy to work the lever briskly with one hand, and each stroke raised the scale nearly one-third of an inch. Forty-seven pounds, hung at the end of the lever, carried it down with a moderate swiftness of working; but a weight of only forty-three pounds remained in equilibrio, and did not descend. Now as the true weight in theory was thirty-two pounds, as deduced from the dimensions of the parts in the manner already done with regard to the small Press, it follows that less than one-third of the actual power was employed to give velocity and overcome all friction.

It may be remarked, that the principal friction in these Presses must be at the circumference of the pistons, and that these do not increase in the simple, but in less than the subduplicate ratio of the power. For if the diameter of the great cylinder were doubled, and every thing else remained unchanged, the surface of its piston, and consequently the power, would be quadrupled, but the friction would be only doubled, and that merely at the leather ring of the greater piston.

As the pressure, in the experiment last mentioned, amounted to 47,040 pounds upon the great piston of four inches diameter, and sixteen circular inches surface, it amounted to 2940 upon each circular inch: now the medium pressure of the atmosphere on a circular inch is nearly twelve pounds, consequently the action was equal to 245 atmospheres, and as each of these corresponds with a column of thirty-four feet of fresh water at a medium, the water in the cylinder was pressed in the same manner as if the whole column had been 8330, or one mile and two-thirds perpendicular height.

Large Presses of this construction are, as has been stated, generally made with two or more pumps of one

2 11

tures.

Strength
necessary to
be given to
Hydraulic
Press cy-
linders.

inch and a quarter bore, and a cylinder of seven inches. These have been used in pressing hay and cotton for packages, and are very effective in producing a greater condensation on the material, with a much less application of moving power and consumption of time.

(427.) After what has been stated respecting the enormous pressures to which the cylinders of these Presses are exposed, it becomes an object of no small importance to estimate correctly the thickness of metal necessary to withstand such internal force. The following investigation on this subject is extracted from a Paper presented to the Society of Civil Engineers by Mr. Barlow. The internal strain on a cylinder was first determined by Mariotte, and Mr. Barlow by a different process arrives at the same conclusion; viz. that the circumferential strain on any given point of the interior of the cylinder is equal to a pressure on a square inch multiplied by the number of inches in the radius. That is, the force tending to rend the cylinder along any line parallel to its axis is equal to a pressure on a section between the circumference and axis. This, as we have said, is the result which has always been deduced by writers on this subject; but in estimating the thickness necessary to resist this strain, it has universally been supposed that all the metal in the thickness opposed an equal resisting power; from which it resulted that in Presses of the same internal diameter the thickness ought to be proportional to the pressure. This principle, however, is known to fail in practice, it having been always found requisite to increase the thickness in a higher ratio than the pressure; and it was principally with a view to correct this error, that the author undertook the investigation, at the earnest request of some of his practical friends; and having completed it, it was presented to the Society of Civil Engineers, who now rank amongst their numbers many of the most distinguished names of the united kingdoms connected with scientific and practical Mechanics.

The following is the particular part of the investigation to which we have alluded, viz. to ascertain the nature of the resistance opposed to any given thickness of metal in a cylinder or ring from internal pressure.

It would appear at first sight that having found the strain on any points, D and C, it would only be necessary to ascertain the thickness of metal to resist this strain, when applied directly to its transverse area. This, however, is by no means the case; for if we imagine, as we must do, that the iron, in consequence of the internal pressure, suffers a certain degree of extension, it will be found that the external circumference participates less in this extension than the interior; and as the resistance is proportional to the extension divided by the length, it follows that the interior circumference and every successive circular lamina from the interior to the exterior surface, offers a less and less resistance to the interior strain. The laws of which decrease of resistance it is at present our object to investigate.

In the first place, it is obvious that whatever extension the cylinder or ring may undergo, there will still be the same quantity of surface in the section of the ring, which area is always proportional to the difference of the squares of the two diameters.

Let D be the interior diameter before pressure, and $D + d$ its diameter when extended by the pressure. Let also D' be the exterior diameter before, and $D' + d'$ the same after the pressure.

Then from what is stated above, we shall have

$$D'^2 - D^2 = (D' + d')^2 - (D + d)^2,$$

or

$$2 D' d' + d'^2 = 2 D d - d^2,$$

whence

$$(2 D' + d') : (2 D - d) :: d : d';$$

or since d and d' are both very small, this becomes

$$D' : D :: d : d'.$$

That is, the extension of the exterior surface is to that of the interior as the interior diameter is to the exterior. But the resistance is as the extension divided by the length; therefore the resistance of the exterior surface is to that of the interior as

$$\frac{D}{D'} : \frac{D'}{D}, \text{ or as } D^2 : D'^2.$$

That is, the resistance offered by each successive lamina is inversely as the square of its diameter, or inversely as the square of its distance from the centre; by means of which law the actual resistance due to any thickness is readily ascertained.

Let r be the interior radius of any cylinder, p the pressure per square inch on the fluid, t the whole thickness of the metal, and x any variable distance from the interior surface. Let also s represent the strain exerted, or the resistance sustained, by the interior lamina, then by the law last deduced

$$(r + x)^2 : r^2 :: s : \frac{r^2 s}{(r + x)^2}$$

= the strain at the distance x from the interior surface; consequently

$$\int \frac{r^2 s dx}{(r + x)^2} + \text{cor}$$

= sum of all the strains; and this, when $x = t$, becomes

$$R = r^2 s \left(\frac{1}{r} - \frac{1}{r + t} \right) = \frac{s r t}{r + t}.$$

That is, the sum of all the variable strains or resistances on the whole thickness t , is equal to the resistance that would be due to the thickness $\frac{r t}{r + t}$ acting uniformly with a resistance s .

Let us now suppose (the above law being established) the radius r , and the pressure per square inch on the fluid p , to be given, to find the thickness necessary to resist it, or such that the strain and resistance may be in equilibrio, the cohesive power of the metal being also given. Let x represent the thickness required, c = the cohesive power of the metal per square inch, then

the greatest strain the thickness $\frac{r x}{r + x}$ can sustain is

$\frac{r x c}{r + x}$, and the strain it has to sustain is $p r$; whence when these are equal we shall have

$$r p = \frac{r x}{r + x} c, \text{ or } p r + p x = x c;$$

whence

$$x = \frac{p r}{c - p}.$$

Hence the following rule for finding the thickness of the metal. Multiply the pressure per square inch by the radius of the cylinder, and divide the product by the difference between the cohesive power of the metal per square inch, and the pressure per square inch and the quotient will be the thickness sought.

Machinery.

Manufac-
tures.

As an example, let it be required to determine the thickness of metal in two Presses, each 12 inches in diameter, in one of which the pressure is $1\frac{1}{2}$ ton per inch circular and in the other 3 tons, the cohesive power of cast iron being 18,000 pounds per square inch.

Here $1\frac{1}{2}$ ton per circular in. = 4278 pounds per sq. in.
3 ditto = 8556 ditto

whence by the rule

$$\frac{4278 \times 6}{18000 - 4278} = 1.87 \text{ inches thickness,}$$

and

$$\frac{8556 \times 6}{1800 - 8556} = 5.44 \text{ ditto;}$$

whereas on the usual principle of computation the latter thickness would be exactly double the former.

Press for
horn, tor-
toise-shell,
&c.
Pl. xxxii.
Fig. 6.

(428.) *Press for pressing horn.*—Horn, tortoise-shell, and other animal substances are capable of being so softened by the application of a moderate heat, that they can be moulded by pressure into any required shape, and the surface may be imprinted with any design in the sharpest and most delicate relief. Another valuable property is, that pieces may be made to adhere firmly together without any cement. The process of forming articles of these substances is extremely simple. The horn or tortoise-shell is boiled in water until it becomes softened, and is then put into moulds of iron or brass, made in two or more pieces, and with cavities between them to correspond with the article which is to be fabricated, and with all its intended ornaments engraved in the interior surface of the mould. This mould being made hot, the horn or shell is put between its two halves, and the mould being put in a small Screw Press, the halves are forced together to imprint the horn and press it into the cavity of the mould. But if the article has any considerable relief, this cannot be done at one heat, and therefore the Press, with the moulds in it, is put into a copper, and boiled still longer; it is then taken out, and by a lever applied to the screw it is screwed tighter, so as at length to obtain the impression desired. When a single piece of horn or tortoise-shell is not sufficiently large to fill the mould, two or more pieces are put together; they are cut to fit to each other with a proper degree of overlap, and being sufficiently softened by boiling in water, the surfaces are forcibly pressed together, and they will thus be united as firmly as if they were originally in one piece. The Screw Press employed for this business is very simple, being only an iron frame with a screw through the top of it; and, for the convenience of putting it in and out of the boiler and copper, a small tackle of pulleys is fixed just over the copper, and by the side of it is a block of stone, with a hole or cavity in it large enough to receive the Press, and hold it firmly upright, whilst a lever or wrench is applied to the screw to turn it round and produce the pressure, which being done, it is again returned into the boiler. To obviate the inconvenience of thus lifting the Press in and out of the boiler, Messrs. Poltzapffell and Deyerlin, of London, have made the Machine represented in plate xxxii. fig. 6, which is a section through its centre. A A is a box or case of cast iron; B a boiler or copper to contain the water; and c the grate for the fire, which is to be placed beneath it to heat the water; E is the flue or chimney, at which the smoke passes off; F F G is a Press, made very strong of cast iron, and capable of being drawn up out of the water and let down into it at pleasure, by means of racks a a at

each side, which are actuated by pinions d d; the axes o of these pinions extend across the Machine, and have each a wheel at the end; these wheels are moved at the same time by two arms or endless screws, cut upon an axis, which extends from one to the other, and is turned by the handle H: the Press is guided in this ascent or descent by grooves in the side of the boiler. When raised up out of the water, the moulds, with the horn or tortoise-shell between them, are put beneath the presser, and a severe pressure is produced by turning the wheel K. This wheel has an endless screw R upon its axis, which works the teeth of a large wheel L, fixed on the top of the screw P. The screw is received into an interior screw formed within the box or presser I, which is guided and prevented turning round by the cross bar e e, through which the presser is fitted; by this means, when the screw P is turned round by the wheel L and endless screw, the horn or tortoise-shell is pressed between the moulds; the Press is then lowered again into the water of the boiler, in order to be still further softened by the boiling; but when the Press is down in the boiler, the screw can be screwed tighter by turning the wheel K until the desired impression is obtained. By turning the handle N the Press is then raised up out of the boiler, and by turning back the wheel K the pressure is released, and the moulds can be removed. The fig. a, b, and c represent a pair of moulds proper for forming a cylindrical snuff-box; a is the internal mould of the box, into the bottom of which a piece of shell, softened by boiling, and cut round, is first placed, and round the inside a long slip is curled, the ends being made to lap over with a proper joint. The external mould b is then put into the cavity of the horn, and is forcibly pressed by the screw so as to give the horn the shape of c when it is withdrawn from the mould: a similar mould is used for making the lid of the box. Small boxes, and those which are slightly raised, can be made from one single piece without joining, also tooth-pick cases and similar articles.

The Chinese are famous for making lanterns of horn very thin and transparent. We are informed in the *Annales des Arts*, that they employ the same methods we do of effecting the joining by softening the horn in hot water, but that they use a long beam or lever for making the pressure. This method is for making up the leaves of horn from small pieces; but as the boiling would disfigure these leaves, they are united together to form the lanterns, by warming them at the fire, and pressing the edges of them together by hot pincers, made flat on the inside; by this means the joints are so perfect that they can scarcely be perceived. See *Repertory of Arts*, Second Series, vol. xxix. where a particular account of the Chinese manufacture may be seen translated from the *Annales des Arts*.

(429.) *Presses used by Bookbinders.*—Three different Presses are employed by bookbinders, but one of them is nothing more than the common upright Press already described; the others which belong exclusively to that trade, are the sewing and cutting Press; the former, however, is only a Press by name, as it is not employed in producing pressure.

Sewing Press.—This is the Machine employed in sewing the sheets together prior to their being put in covers. It consists of a bed of hard wood of such thickness as to prevent its warping, the width of the largest size books, and about two feet or two and a half feet in length; a groove is cut through it which extends nearly

Machinery.

Manufac-
tures.

its whole length, and about an inch within one of its edges, and the same or a little less in breadth. At the extremities of this are erected two wooden screws furnished with nuts, and on these nuts rests a cross piece having two holes at its ends for passing it over the screws; the middle part of this cross bar is turned round, leaving that part containing the two holes broad and flat; between this bar and the opening in the bed are fixed lines, which are tightened at pleasure by means of the wooden nuts, and being all brought to a uniform degree of tension, the several sheets of the work to be bound are successively sewed to these lines. It should be observed that the lines below are held and fixed to their places by means of small keys in or under the bed of the Press. In old binding, and occasionally in modern binding, these lines or cords lie projecting at the back of the book, but more commonly now the back of the sheets, after being properly arranged and secured in another Press, have small grooves cut across where the lines are to be fixed, which are thus countersunk, and the back of the book is left smooth and level.

Bookbind-
er's cutting
Press.

(430.) *Cutting Press*.—This is a Press used for cutting and squaring the edges and ends of the sheets, and is used as well by pasteboard makers as by binders and stationers. It consists of two heavy pieces of wood in form of cheeks, connected by two strong wooden screws, which being turned by an iron bar draw together or set asunder the cheeks, as much as is necessary for putting in the books or paper to be cut. The cheeks are laid horizontally, commonly over a box or chest for receiving the cuttings. On the side of the cheeks are two pieces of wood of the same length as and fixed parallel with the screws which serve to direct the cheeks, and to prevent their opening unequally. This, in fact, constitutes the press part of the Machine, but there is always accompanying it a plough for cutting the paper; this plough slides on a fillet on the upper side of the cheek, carrying a cutting knife, which may be advanced by means of a screw so as to cut successively through the whole thickness: it is also removable for the purpose of being sharpened.

The plough consists of several parts, *viz.* a wooden screw or worm, which catching within the nuts of the two feet which sustain it on the cheeks, brings the knife to the book or paper, which is fastened in the Press between two boards. This screw has two directors, which resemble those of the screws of the Press. To make the plough slide square and even on the cheeks, so that the knife may make an equal paring, that foot of the plough where the knife is not fixed slides on a fillet or in a kind of groove fastened along one of the cheeks. The knife itself is a piece of steel, five, six, or seven inches long, flat, thin, and sharp, terminating at one end in a point; at the other end it is square for the convenience of fastening the plough.

Improved
stationer's
Press.

(431.) An improved form for a stationer's cutting Press was in 1833 presented to the Society of Arts by Mr. M. Staunton, two elevations of which we have given in plate xxxiv. fig. 6, 7, is the Press having the front of the cutting tub or chest removed, in order to see the interior: *a* is an additional board, having two equally divided scales *b b* inlaid in the front part, the thickness of the Press being allowed for in the measures. This board receives the adjusting or movable shelf *c*, on which the paper is placed to be cut, the shelf moving up and down by two screws which are fixed in it, and pass through the perforations *d d*; these screws are fixed by nuts at the

back of the board, as shown in the end view, fig. 6. Machinery These two scales enable the workman to set the board strictly level at any required height within the range of the scales, by adjusting it to the corresponding measure on each. The board *a* slides perpendicularly into its place in the framework *e f*, fixed within the cutting tub or chest. There are three studs, *g g g*, one on the top of the centre of the board *a*, another on the framework *e*, and the third on the part *f*. On the under side of the left cheek of the Press are three corresponding sockets, which fit on the studs, and thereby fix the Press and board *a* correctly together: the Press lies on the usual ledges *h h* exactly at right angles with the board *a*, and therefore the paper when resting on the shelf *c* and screwed in the Press is always kept upright. See *Transactions of Society of Arts*, vol. xlix.

(432.) We might enumerate many other Presses used in different mechanical processes, which, however, except those of the most simple kind, are found described under the articles treating of the respective subjects. Of the simpler kind we may mention

The *joiner's Press*, used by them to keep close the panels, &c., of wainscot, doors, &c. This consists of two screws and two pieces of wood four or five inches square, and two or three feet long, whereof the holes at the two ends serve for nuts to the screws.

Founder's Press.—This is a strong square frame consisting of four pieces of wood firmly joined together with tenons, &c. It is of various sizes; two of them are required to each mould, at the two extremes of which they are placed, so that by driving wooden wedges between the mould and frame or sides of the Press, the two parts of the mould for the metal may be pressed close together.

Presses for making cider, and other processes of a similar kind, differ in no respect from the common Press for packing, except that here the descending board commonly enters into a box or vessels, with holes to allow the juice or liquid expressed to issue out into proper vessels placed to receive it.

For Printing Press, Copperplate Press, &c. see PRINTING.

Proving Machines.

(433.) *Machines for proving the strength of chain cables*.—Since the very general introduction of chain cables into the British Navy, it has been thought essential to the safety of the service that every cable before it is issued from the stores shall be submitted to a certain strain according to the dimensions of the bolt from which it is formed, a certain proof being fixed for every description of cable. As the strains thus ordered to be brought on the cable, and particularly those of the larger kind, are very considerable, Captain Brown, the original inventor of the chain cable, had a Machine constructed on his premises at Millbank, Poplar, for this purpose; in which about one-sixth of the length of the cable was laid in a long bed with one end fixed to the extremity of a system of heavy levers well balanced, and the other to a system of wheels and axles worked by manual strength. The chain was thus stretched between the two extreme points, and the amount of the strain was estimated by the weights introduced at the other end of the system of levers. Afterwards Mr. Brunton, who took out a patent for an improved form of the chain cable, had at his Manufactory in the City Road, a proving Machine erected of an entirely different description. Here was of

Proving
Machines
for iron
cables.

Manufac-
tures.

course a long bed as in the former Machine, but one end of the cable was attached to a fixed point, and the other to the piston rod of an Hydrostatic Press; and the amount of strain was estimated by a small valve placed in the side of the body of the Press, every pound on the valve answering to about sixteen thousand times that amount of strain. These were both objectionable, or at least at variance with each other, the multiple of power in the last and the inertia and friction of the levers in the former were very great, and the result differing very considerably, they could not be safely depended upon. It appears, indeed, from Barlow's *Essay on the Strength of Iron*, in some experiments which the author made on both these Machines, that with different parts of the same iron bolt there resulted a difference of several tons, the general averages of the strengths on Brown's Machine being to those on Brunton's as fifty to fifty-nine. The Admiralty, unwilling to trust to these uncertain measures of the strength of their cables, have lately erected at Woolwich a Machine intended wholly for this purpose, which combines both the former means of estimation, and in which the levers are so nicely balanced and hung on knife-edges as to turn with an ounce weight in the scale, even when acting with a strain of many tons. The estimation by the water pressure was intended to register the same; but the friction is so great upon the rod which acts on the balance, that it is impossible to distinguish a change for several additional tons of strain, and this friction of course increases as the strain increases; this register is, therefore, but little regarded, and, indeed, as the other acts with so much freedom, it is not necessary. In order to prove the truth of the lever register there is a means provided for trying the balance against actual weights to the amount of four tons.

Proving
Machine
by Bramah.

This Machine was erected by Messrs. Bramah of Pimlico, and is no doubt one of the most perfect of the kind which has been executed. It consists of two cast iron sides cast in lengths of 9.5 feet each, with proper flanches for abutting against each other, and for securing the whole to sleepers resting on a secure stone foundation. The whole length of the frame is 104.5 feet, equal to one-sixth the length of a cable for a first-rate, so that the cables are tested in that number of detached lengths which are afterwards united by link bolts. The Press is securely bolted to the frame at one end of the same, and the cylinder is open at both ends. The solid piston is $5\frac{1}{4}$ inches in diameter in front, and $10\frac{1}{2}$ inches behind, so that the surface of pressure is the difference of the two

$$= \left(\frac{21^2}{2} - \frac{21^2}{4} \right) \times .7854 = 65.5 \text{ inches.}$$

The system of

levers hung on knife-edges are attached to the other end of the frame, and the cable is attached by bolt links to this and to the end of the piston rod. The first lever being properly balanced, and the cable attached to a short arm rising above the axis, this draws the other arm downwards, and at a distance equal to twelve times the short arm is a descending pin and ball; this acts in a cup placed on the upper part of the arm of the second lever, and this again acts on a third. The first two levers are under the floor, and pass ultimately into an adjacent room, where a scale carrying weights is conveniently placed, and the whole combination is such that every pound in the scale is the measure of a ton strain; and, as we have stated, the whole acts with such precision that one pound more or less in the scale very sensibly affects the balance. At

the same place is situated the scale, acted upon by the water pressure from the charge pipe of the Press; and the valve in this pipe is of such dimensions that, together with the lever by which it acts, the power is again such that a pound should balance a ton; but, as above stated, the friction is here so great, that it requires several pounds to make a sensible change in the apparent balance, and for this reason this scale is seldom used. The forcing pumps are in another adjacent room, and are worked by handles after the manner of a fire engine. At first, six pistons are acting, and the operation proceeds quickly; but as the pressure and strains increase, the barrels are successively shut off, till at length the whole power of the men is employed on one pump only, and on this the action is continued till the proof strain is brought on the cable. A communication is then opened between the cistern and cylinder, and every thing is again restored to equilibrium.

The following experiments show the strain actually employed to break chains and chain cables of different dimensions, according to the report of Captain Brown on his lever Machine.

Experi-
ments on
the strength
of chains
and cables.

	Tons. Cwts.	
$1\frac{1}{2}$ inch. Old sable, $1\frac{1}{2}$ inch square bars, cut into pieces 2 feet long, piled and rolled into bolts of $1\frac{1}{2}$ inch	73	10
$1\frac{1}{2}$ inch. Old sable, ditto, ditto	80	0
$1\frac{1}{2}$ inch. Gurcoft new sable, ditto, ditto	71	0
$1\frac{1}{2}$ inch. Keiolsken, Archangel, inch square bars, cut into lengths of 2 feet, piled, and rolled into bolts	71	0
$1\frac{1}{2}$ inch. Old bolts, found promiscuously, piled and fagoted by hand hammers at my works .	71	10
$1\frac{1}{2}$ inch full. English bars, piled and rolled .	86	0
$1\frac{1}{2}$ inch bore. Ditto, ditto	80	0

Twelve further experiments, made 13th September, 1816.

	Tons. Cwts.	
$1\frac{1}{2}$ inch. Old Dutch bolts, fagoted by hand hammers at my works	71	0
$\frac{1}{2}$ inch. No. 1, $\frac{5}{8}$ square, (Welsh iron,) hammered into blooms, and rolled into bolts, at the King and Queen works	78	10
$1\frac{1}{2}$ inch. No. 2, $\frac{3}{4}$ inch square, (Welsh,) manufactured as above	73	5
$1\frac{1}{2}$ inch. No. 4, (Welsh iron,) fagoted by hand hammers at my works	88	10
$1\frac{1}{2}$ inch. No. 6, $\frac{5}{8}$ inch square ditto, rolled, but not hammered, at the King and Queen works	76	0
$1\frac{1}{2}$ inch. King and Queen scrap iron	80	5

The links of these chains were of an oval-like form, 6 inches in the clear.

The mean of these experiments gives 76 tons for the strength of a double bolt of $1\frac{1}{2}$ inch diameter in the cable form, which corresponds to about $21\frac{1}{2}$ tons per square inch section. Now by the same Machine the mean strength of malleable iron per square inch is 26 tons; therefore the strength of iron in the cable form is to that of the simple bolt in about the ratio of 43 to 50. But the links of these chains were without stays. Brunton's patent consisted of introducing a broad ended stay of cast iron between the sides of the link, giving them the shape of an oval, which was found to add very considerably to their strength, the strain required in this form to break them being nearly as great

Manufac-
tures.

as that for the iron in its simple bolt form, so that the stay may be said to increase the strength by about one-sixth part; at the same time, however, it must be considered that the weight is also increased, although in a less ratio.

Machines
for proving
ordnance,
éprouvette.

(434.) *Machines for proving Ordnance.*—One of the first steps in proving ordnance is to prove the strength of the gunpowder, by which the powder proof of the gun is made, and this is done by what is called an *éprouvette*. This consists of a small brass gun suspended by an iron strap and bar from two points towards the muzzle and breech; the two bars unite above, and are attached to an axle, which lies across a strong frame mounted on wheels, to transport it from place to place; a graduated arc is also fixed to the axis which vibrates with the gun, and is graduated from 0 to the full extent of the arc. An index and bar move on the axis, the friction on the axis being only sufficient to allow the bar to remain in any part where it is placed, the index sliding over the arc like the index of a common quadrant: there is also a small adjusting screw attached to the index bar, by which, after the gun is charged, the index may be adjusted accurately to zero.

Conceive, now, the gun charged with a given small charge of powder, and left to take up its natural swinging position; the bar is brought down to the position in which the screw reaches the upper part of the frame; and if the index is not exactly at zero, it is adjusted to it by means of the screw. The powder being now fired, the gun recoils with the quadrant or graduated arc, but the index

The following Table shows the different kinds of best Machinery. bower cables at present employed in the British Navy, with the corresponding iron cables, and the strain to which each is respectively submitted.

remains in its place, being prevented from recoiling by the stop or screw; but in the returning vibration the friction on the axis and that of the index on the arc is sufficient to retain it in its place, and therefore when the motion of the gun subsides, the quantity of recoil, which is the measure of the strength of the powder, is shown by the index on the arc. Dr. Hutton, who made numerous experiments on this Machine, has the following remarks upon the use of it. "It is not," he says, "confined to any one particular size, or even shape; it may be either a short cannon or a mortar, the latter probably the best, and these may be either small or large. The present instrument, with a small cannon, is to be considered only as a model of the cannon sort, to be used and charged with two or three ounces of powder, and with which a multitude of experiments have been made with perfect satisfaction; the results, even from this size, being remarkably regular. If it be desired to try large charges, then a larger mortar or gun may be employed in the same way; but the present small one is quite sufficiently accurate and regular. Though the experiments that have been tried with this *éprouvette*, have mostly been with two ounces of powder, as a convenient medium charge, yet it is equally accurate with either more or less than that quantity; and it is remarkable, that it shows the slightest variation that has been made, either in the strength or the quantity of the powder.

"The instrument is so expeditious, simple, and easy in practice, that any common soldier, or other person, can learn the use of it completely in five minutes, employing it with safety and expedition, and setting down a register of his trials. So that we have thus united in the same Machine the valuable qualities of accuracy, uniformity, ease, and expedition.

"The Machine can easily be made, too, by any artist, from the preceding description of its construction; or

Manufac-
tures.

it can be executed at home, and sent to distant places, namely, the small parts of it, and there fixed to any small mortar or swivel gun."

In the use of this instrument for the constant regular practice of proving gunpowder, a certain mark or number of the divisions on the arch line may be fixed on, as a standard for the strength of the powder, which mark or number of divisions may be ascertained by charging it with any powder of approved strength or quality. And when once that mark or number is known, the Machine will uniformly rise to the same place at every trial, either accurately or within a small fraction, with the same quantity and strength of powder. But should any other quality of powder be used, the Machine will show the difference in its strength with the utmost nicety whether above or below the proof.

Method of
using the
éprouvette.

To practice with the éprouvette.—Charge it with two ounces, or any greater or less quantity of powder put in loose, without using any bag or cartridge, and without any ball, in the following manner. Pour the powder carefully into the ladle; then, as the piece hangs at rest in the horizontal position, introduce the ladle with the powder carefully into it, to the very bottom of the bore; as the ladle lies in this state, let an assistant push the gun gently forward a little, to raise the muzzle higher than the breech, and while he supports it in this position, turn the ladle of powder half round, to let the powder drop all out in the bottom of the bore; after which draw out the ladle, and introduce the other or flat end of it, with which press the powder lightly all together in the bore, and then let the gun gently down again into the horizontal position.

After the gun has been thus charged with powder, and before firing it, the index must be set exactly to the beginning of the divisions on the arch. This is done by first setting it near the mark with the hand, and afterwards bringing it exactly to it, by means of a screw in the other end of the index, above the stand of the Machine. In this manner, with one hand press the upper or screw-end of the index down upon the bar of the stand, and at the same time with the other hand turn the screw backward or forward, and you will perceive the lower end of the index; by that means move slowly backward or forward, till it come exactly to the beginning of the divisions.

Before firing the powder, observe to have the socket of the index, which fits upon the horizontal axis of the Machine, always pressed to it with a moderate degree of friction; so that it may not sensibly obstruct the vibratory recoil of the gun, and yet that the index may keep any position you give it, without slipping from the arch or the axis, as the gun returns again from the first vibration.

After the piece has been charged with the powder, and the index set exactly to the beginning of the divisions on the arch, as before described, it is to be fired by means of a thread of quick-match in the following manner. Take about three or four inches of fine quick-match, and introduce one end into the vent till it touch the powder in the bore, leaving the remainder to hang loose on the outside; then set fire to this with the port-fire, plucking this quickly away lest it should be struck with the stem that suspends the gun, which would somewhat check the recoil. After the gun returns from the recoil, stop the vibrations gently, without touching the index, and look what division on the arch the index points to, or stands at, which number will

show the strength of the charge. For more satisfaction, the same charge must be repeated two or three times, and the medium of all the numbers taken for the strength of the charge.

It must not be understood, however, that this proof by éprouvette, which is always employed before a gun is submitted to the powder proof, is the only proof which powder undergoes, this kind of proof being, in fact, only to ascertain that the powder retains the original force it had at its first examination.

(435.) Proving gunpowder.—The first step in examining gunpowder is by rubbing it between the hands for a few seconds, to find whether it contains any irregular hard lumps. The second is by blasting about two drachms of it upon a copper plate, and comparing the effect with that of an approved sort of powder. In this proof it should not emit any sparks, nor leave any beads or foulness on the copper. This being satisfactorily passed, it is submitted to a proof of strength by mortar or by the gun éprouvette above described.

The mortar proof consists in projecting a 68-pounder iron shot from an 8-inch Gomer mortar, at 45 degrees' elevation, with a charge of four ounces. In this proof powder, new from the mills, must give a range of not less than 380 feet; and powder that has been issued and returned into store, or regenerated and restoved powder, a range of not less than 350 feet.

By the gun éprouvette, with a charge of two ounces with the first of the above powders, the index of the éprouvette must describe an arc of 21 degrees; and with the other descriptions, an arc of not less than 20 degrees 30 minutes.

The proof of fine-grained or small-arm powder is with a charge of two drachms from a carbine barrel, to perforate with a steel ball a certain number of half-inch elm boards, wetted and placed three-quarters of an inch asunder, the first being 39 feet 10 inches from the mouth of the barrel. The best powder generally propels the ball through 15 or 16, and the restoved powder through from 9 to 12 of these boards. This powder is likewise submitted to proof by the gun éprouvette with a charge of two ounces, and the arcs described should be with powder new from the mills, not less than 26 degrees; and with restoved and all other descriptions of powder, not less than 24 degrees.

The last trial of powder is by exposing about one pound of each sort, accurately weighed, to the atmosphere for seventeen or eighteen days; during which time if the materials be pure, it will not increase at all considerably in weight by attracting moisture from the air. In this exposure, one hundred pounds of good powder should not imbibe more than twelve ounces of moisture, or somewhat less than one per cent.

Powder Marks.

The different sorts of powder are distinguished by the following marks on the heads of the barrels.

- | | | |

| R. A. | For rifle arms. | } Marked in blue |
| L. G. | Large grain. | |
| F. G. | Fine grain. | |
| R. S. | Restoved. | |

(436.) Proving balls and shells.—When a quantity of balls and shells are delivered into store, they undergo an examination and gauging, and afterwards the shells are submitted to a proof by the water process, to see that

Machinery.

Proving
gunpowder.

Proving
balls and
shells.

Manufac-
tures.

they are free from holes, cracks, &c. As in the state in which the balls and shells are received, they are commonly covered with rust, sand, &c., they are first cleaned carefully on the outside, by scraping off the rust and picking out any pieces of dirt which may get into external holes on the surface and hide blemishes which are fatal to the reception of the ball when detected. This process is carried on by hand in the larger kind of shells, but in the balls and smaller shells a Machine is employed, which is very simple in its construction, and effective in its operation. It consists of two circular plates of cast iron about two feet in diameter, fixed on an axle about three feet apart, and from one circumference to the other there pass a number of bars of iron about an inch square, and at about an inch distance from each other, forming a sort of drum or cage resembling a squirrel's cage; a door turning on a hinge is formed in one of the cast iron ends, large enough to introduce an eighteen-pound ball. Fifteen such balls weighing two hundred and seventy pounds, or more of a smaller kind, are introduced into the door, which is then securely shut, and by means of a winch at each end of the axle four men are employed to turn the drum round pretty smartly, the balls during the time rolling and grinding against each other and the iron bars above mentioned, till in about ten or fifteen minutes they are found to be freed from all the superficial rust; the door is then opened and they are taken out to be examined with respect to any deep holes or splits on their surface, and any such being found the ball is rejected, as such defects are found to interfere greatly with good and efficient practice. It should have been observed that the iron drum is suspended in a strong iron frame, which frame is supported on a transverse axle below its middle, and is held up or secured in front by an iron pin, so that when the balls are cleaned the pin may be withdrawn and the drum and carriage tilted endways, whereby the balls are delivered into a spout and conducted away to a little distance to undergo their further examination. The whole frame and drum are also mounted on an iron carriage with four wheels, whereby it may be transferred to any place instead of bringing, as was formerly done, all the balls to the Machine which was fixed in its place. This process being gone through, and the surfaces examined for holes, &c. as above described, the low gauge is applied to every ball. This gauge is a ring of iron very accurately turned to a given diameter, which is a little less than the diameter of the ball ought to be; a handle is attached to the gauge, and a man holding the handle tries the gauge to the ball, and if the latter passes the gauge, it is too small and is rejected; if not, another gauge called the high gauge is tried. This consists of a cylinder very accurately bored to a diameter a very little exceeding that of the ball: this cylinder is about eighteen inches long, and every ball which, after the preceding trials, will pass through it, is admitted, but if it sticks in its passage it is rejected. The balls which thus pass through the second gauge are immediately painted over with a thin composition of Grant's black and red lead and placed on the pile for future service.

It has been already observed that the larger sort of shells are all examined by hand. This process is carried on by means of old swords having a handle fixed on at each end of a broken blade; with these they are scraped all over to loosen all the sand that may be remaining; and internally all sand and other matter is removed, and

a strong puff from a pair of bellows is blown into them Machinery. by which the dust is forced out at the fuse hole. They are then examined by means of instruments to ascertain that they are concentric, and an empty fuse is driven into the fuse holes. The shell is then suspended in a vessel of water in such a manner as to be just covered but without admitting any water at the fuse. In this situation the nozzle of a pair of bellows is inserted into the empty fuse, and a strong compression of the air is made within; if in this process no bubbles of air rise in the water the shell is concluded to be sound and serviceable. When shells are condemned as unserviceable, the reason for condemning them is expressed by one of the following marks, — F — which implies a faulty fuse hole, or N X non concentric; W X faulty by water proof.

(437.) *Proof of guns.*—After the pains which are thus bestowed upon proving the accuracy and soundness of the balls and shells, it will readily be imagined that great care is taken to ascertain that the guns themselves are free from all kinds of flaws and defects. Proving guns and powder.

The first important inquiry is to determine whether the bore is every where of its proper dimensions; this is done by a long and very accurate parallel ruler formed of two perfectly straight steel bars, exceeding in length any of the ordnance at present used in the British service. The two bars forming the parallel ruler are united together at different parts of their length by uniting plates as in the common parallel ruler, (which has however commonly but two,) and all these are acted upon by one long bar which turns by a handle at the end, so that they may be opened to any proper distance and remain perfectly parallel. When properly opened, the ruler is introduced into the bore, and in order to prove whether the sides of the bore are parallel to these rods and to each other, another instrument is introduced. This is a long rod having another attached to it at one-fourth of its length from the lower end, and which are opened from each other by means of a spring at the upper end; a smaller roller is fixed at one end, and as the instrument is passed down the bore in contact with the edge of the parallel bar, the roller is kept pressed by the spring above mentioned against the side of the bore, and any deviation from true parallelism is magnified in the ratio of the lengths of the arms, that is as four to one, which is shown by an index attached to the end of the instrument. When the bore is every where true, and when, of course, the side of the bore is every where equidistant from the parallel bar, the index remains stationary through the trial; but if there is any want of accuracy in the boring, the ends will be compressed or expanded as the rod is passed down, and if it exceeds a certain quantity the gun is rejected.

This examination being passed, another instrument is employed to search for any holes which may occur in the sides of the bore. This is a long round wooden rod, perforated from end to end through its length. At one end are fixed a number of steel rods with points or hooks at their ends, and formed so as to spring open, but which are compressed together by an iron ring which encompasses them; this ring being fixed to an iron wire which passes through the rod, so that a person by means of this rod and ring can open or close the searcher at pleasure, or rather he may close them by forcing the ring upwards, but they spring open of themselves when the ring is pulled down. In using this instrument the ring is forced up and the rods are com-

Manufac-
tures.

pressed, it is then introduced into the gun, and when at the breech the ring is pulled down by means of the rod above referred to. When this is done, the points of the searchers are by the natural spring given to the rods pressed against the side of the bore, and a labourer now works the rod about in all directions, and if any holes are present some one of the points is pretty sure to find its way in. Such being the case, the situation is carefully measured and another instrument is used to measure its depth, and if it exceeds a certain quantity the gun is condemned.

The proof having been thus far satisfactory, it is next to be submitted to the powder proof. This consists of charging the guns with a larger quantity of powder than constitutes the full practice charge; that is, the full charge being about one-third the weight of the ball, the proof charge is taken generally about half the weight of the ball, and sometimes two balls are introduced. The guns being thus charged, are placed on sleepers on the ground in the face of a high mound, a match and train are laid from one to another, and every person being removed to a safe distance, the train is fired and the guns successively deposit their balls into the mound. All that have sustained this proof are now submitted to the final water proof, which consists in forcing water into them under very considerable pressure; and if in this no signs are exhibited of the water penetrating through the metal, the gun is considered fit for service, and marked and reported serviceable accordingly. But it sometimes happens that after the gun has gone through all the former trials, the water proof will discover flaws which had evaded detection by all the other methods, the water sometimes issuing in a stream, and in others the whole surface becomes covered with a sort of dew through the pores of the metal; in either of which cases the piece is condemned. In iron guns there is in no case to be allowed in the length of the bore a variation exceeding .3 of an inch; in the diameter of the bore only .033 of an inch is allowed from a 42-pounder to an 18-pounder, and .025 of an inch from a 12-pounder to a 4-pounder; and in the position of the bore .25 of an inch out of the axis from a 42-pounder to an 18-pounder, and .334 of an inch from a 12-pounder to a 4-pounder is allowed. They are fired twice with the regulated charge with one shot and two high junk wads, and examined with the searcher above described after each round. In this examination they must not have any hole or cavity in the bore of .2 of an inch in depth behind the first reinforce ring, or .25 of an inch before the ring.

In brass guns the diameter of the bore must not vary more than .025 of an inch from the true caliber, and in the other dimensions in no case more than .2 of an inch. The regulated charges for these guns are as follows:

12-pounder,	} double full practice charge.
9 ditto,	
6 ditto heavy,	
6 ditto light,	} three times the practice charge.
3 ditto,	

Any hole or cavity .15 of an inch deep upwards or sideways in the bore, or .1 of an inch in the bottom between the breech and the first reinforce ring, or .2 of an inch upwards or sideways, or .15 in the bottom of the bore before the first reinforce ring, is considered sufficient to condemn them.

In mortars and howitzers the exterior dimensions are in no respect to deviate more than .1 of an inch in the

10 and 8-inch howitzers, and .05 of an inch in the 24 and 12-pounder howitzers, and Royal and Coehorn mortars and howitzers. Their bores and chambers must not deviate from their true diameters or positions more than .25 of an inch.

The brass mortars and howitzers are fired twice with their chambers full of powder and an iron shell; the mortars on their beds, at an elevation of about 75 degrees; and the howitzers on their carriages, at an elevation of about 12 degrees. The iron mortars are proved with a charge equal to the full chamber, and an iron shot equal in diameter to the shell.

In carronades, the bores and chambers must not deviate more than .05 of an inch from their true dimensions and positions. They are proved with two rounds, with their chambers full of powder and one shot and wad. A hole of .2 of an inch in depth in the bore, or of .1 of an inch in the chamber, condemns the piece. All ordnance, after having undergone these proofs and the subsequent searchings, are subjected as above stated to the water proof. This is done by means of a forcing pump, having a pipe or hose fitted and secured to the mouth of the piece, and a plug to stop up the vent. After two or three efforts to force the water through any honeycombs or flaws which there may be in the bore, they are left to dry, and generally the next day examined by light reflected from a mirror. If the bore should contain any small holes or flaws which have not been discovered by the former proofs, they are very readily found by this, as the water will continue to weep or run from the holes after the solid parts of the bore are perfectly dry.

When ordnance is suspected to be of bad quality, it is often subjected to a more rigorous proof, such as firing twenty rounds rapidly with a charge of powder equal to the shot's weight and two shot; and in doubtful cases, where the purity of the metal is suspected, recourse has been had to chemical trials and analysis. A quantity of clean filings, taken from a part of the iron free from rust, are dissolved in diluted sulphuric acid and the quantity of gas discharged. The plumbago which remains after solution is also separated by filtration and carefully weighed. Now it is a well known fact that the purer the iron, the greater is the quantity of inflammable gas obtained, and the less is the proportion of plumbago which remains after the solution. From these parts, therefore, a tolerable judgment may be formed of the quality of the metal: when the plumbago exceeds four and a half per cent. the iron will always be found deficient in strength, and there has been no instance of a gun bursting where the plumbago did not exceed three per cent.; that is, where one hundred grains of the metal did not leave more than three grains of plumbago. The colour of the plumbago is also to be attended to; when it is brown or reddish it is an indication of hard metal, and when in quantities and mixed with foreign substances, there can be no doubt but that the iron is too soft.

When ordnance is condemned as unserviceable for any of the foregoing reasons, it is marked as follows: — D × for faulty in their dimensions, S × by searcher, and W × by water proof.

(438.) *Punching Machines.*—There are a great variety of Machines falling under this description, their general purpose being to punch out parts from a plate of rolled metal: in some cases the part punched out is the object in view, as in cutting the blanks for coin, buttons, &c.;

Manufac-
tures.

in others the part of the plate remaining after the holes have been formed or cut away is the part to be preserved, as in forming the fronts to ornamental steel and brass fenders, &c. The processes of cutting blanks for coin and buttons will be described under the articles Coining and Button making, and we shall therefore in this place speak only of what is properly called punching, in which part of the plate remaining after the operation is to be preserved.

Punching
iron plates

(439.) *Punching iron plates.*—There are various cases in the present state of the Mechanical Arts where the old process of drilling holes was formerly employed, which is now superseded by punching, and with a rapidity which is truly astonishing. In making steam engine boilers, either of sheet iron or copper, the several plates must be securely rivetted together; and the number of holes requisite to effect this is very great, as is also the power which at one impression shall cut a clean hole through a sheet of iron of half an inch or more thick. Yet this is done with such rapidity, accuracy, and apparent ease, as never fail to be highly interesting to the stranger who visits our Manufactories in which such work is under operation. The holes in the several plates which are to be united must necessarily be formed at very equal distances to admit the passage of the bolt, and they must be very exactly of the same size that the same bolt may accurately fit both. This bolt or rivet, when the plates are placed together, is introduced red hot by a man inside, who holds the head of a heavy hammer against the inside head of the bolt, while the man outside by repeated blows on the red-hot bolt forms the head outside and thus secures the plates together.

Machines for punching may be worked by steam or horse power, or by a man; for notwithstanding it would be very difficult so to arrange a Machine as to enable a man by the application of his strength to punch a hole of half an inch diameter in a plate of iron half an inch thick, yet by allowing him to accumulate his power by means of a heavy fly wheel, the operation is performed after the fly is once in motion with apparent ease. The general character of these Machines is, that a long lever is suspended near to one end which carries the punch, the other end resting on an eccentric turned as above stated, and which, by pressing this long heavy end upwards, depresses the other with great force, and thereby forms the hole required. In the subsequent part of the revolution the weight of the long arm of the lever makes it descend with the low part of the eccentric; this raises the punch and allows the iron to be moved on its bed to receive the next pressure.

Pl. xxxv.
Fig. 1.

A Machine of rather a lighter description is represented in plate xxxv. fig. 1. It is fixed upon a strong metal framework or bed *a a*, and is worked by horse power; a band is passed round the drum *c*, fixed on the axis of the fly wheel *d*, which communicates the motion to the pinion *e*, taking into the toothed wheel *f*; these wheels work in plummer blocks, supported on the upright frame *g g*. On the axis of the wheel *f* is placed the crank and roller *h* of the lever *i*, the fulcrum of the lever being placed at *k*; the iron to be punched is placed under the punch *l l*, sliding through the triangular case *m*, fastened together by flanches supported by the projecting piece of metal *n*. The piece punched out drops into a cavity made in the stone bed *o*, and shown by dotted lines. In the revolution of the fly, the lever *i* being raised causes the steel cutters *p p* to approach each other, and the punch *l l*, sliding through the case *m*, is de-

pressed; thus performing very accurately the operation of cutting and punching at one time. The length of the iron to be cut is regulated by an upright gauge on the other side of the Machine, against which the iron is thrust from the side; *q* is a guide frame for the lever.

It would be endless to describe the different forms of punching Machines and the different objects for which they are employed. They are used not only for the cases above described, but for all sorts of open ornamental work: for punching cards for weaving damask, for punching small holes in copper, brass, and iron plates for various useful purposes in different Arts and Manufactures, &c. &c. A patent for a Machine of the latter description was taken out a few years back which is exceedingly ingenious, and has, we believe, been found valuable.

(440.) The apparatus to which this patent relates is represented as being joined to a common fly Press; but it is obvious that it may be also united to various other Presses. To the bottom of the screw of the Press a vertical sliding part is connected, secured so by lateral pieces as to move up and down with the screw perfectly, steadily, and evenly, without any shake or deviation. The lower surface of this sliding part is to be made exactly horizontal, flat, and level, and of course is to be of a sufficient size to properly bear up and act on the punch plate, which is to be attached to it by screws. This punch plate, which in the first instance is supposed to be prepared for making a single row of holes, has a number of holes drilled in it in one line, at such distances apart as are suitable to the nature of the work to be executed; which holes are enlarged or countersunk at top to receive the heads of the punches, and thereby draw them up out of the work when the slide is raised. The punches are made of steel wire, properly hardened and tempered, and have their heads enlarged to fit the countersunk cavities prepared for them in the plate, either by hammering the heads at the sides, or by *setting them up* by hammering their upper surfaces.

Corresponding to this row of punches a matrice is to be prepared, having holes drilled in it exactly to fit the lower ends of the punches, in order that these may cut through the materials, which they are to perforate quite cleanly, and without leaving any burs; and the punches themselves must be made very level at their lower surfaces for the same purpose. The matrice must be very evenly and firmly fixed exactly under the punch plate, on the bench that supports the Press, so that the punches may enter it without any deviation, and be withdrawn again without experiencing adhesion in any part.

The part of the apparatus for holding the metallic plate, on which the punches and matrice above described are to act, consists of a horizontal frame of cast iron, within which another frame is fitted so as to slide back and forwards horizontally very evenly and steadily, and secured from deviation by side pieces screwed to the fixed frame, so as to effect this purpose. This sliding frame is made to move backwards and forwards by a long horizontal screw placed beneath it, near the head of which a groove is cut to receive a collar, attached to the end of the fixed frame in which it turns; and which collar, by being divided into two equal portions, is capable of being fitted more exactly to the groove, so as to preclude all shaking of the parts; the avoiding of which is very necessary for the perfection of the work to be performed by the engine. The metallic plate, which

Mach. nery.

Patent
punching
Machine.

Manufactures.

is to be perforated, is fastened to the two extremities of the movable frame by two or more cramps or small vices, the screws of which enter the plates of the frame, one of which plates is movable in the direction of the motion of the frame, to which it is fastened by horizontal screws running in the same direction, which screws, after the metallic plate is fastened in as described, draw it out to the full extent so as to make it lie quite even and level during the action of the punches.

This horizontal plate holder is fixed on a level with the top of the matrice on the press bench, so as to draw the plate evenly over it; and the row of punches being of course placed at right angles to the direction of the long screw, by which the sliding frame is moved, the distance asunder between the rows of holes formed in the metallic plate by the punches, will depend on the degree to which this long horizontal screw is turned round. To regulate which more exactly, its head is furnished with a ratchet wheel, divided into a number of spaces or teeth corresponding to the portion of the revolution of the long screw required to produce the intervals between the rows of holes in the plate; and a spring click or catch, acting on its ratchet wheel, shows when the horizontal screw has been turned sufficiently for a fresh row of perforations.

This simple form of the ratchet wheel and catch will be sufficient for large work, in which the perforations are not very close together; but when fine work is to be executed, in which the spaces between the holes are very small, a pinion is fixed on the head of the screw, which turns round a toothed wheel that is so much larger as the rows of holes are to be closer together; and pins, projecting from the face of the large wheels that come in contact with the end of the lever or hinged stop, regulate the space which the screw is to be turned for the purpose required.

It is plain that the relative sizes of the pinion and wheel may be so varied that the number of projecting pins may be either increased or so diminished that even one will serve for the purpose; an instance of which latter proportions is represented in the drawings of the specification.

It may be readily conceived how several rows of punches may be fixed in one plate on the same principle as the single row already described, so as to cut out all the holes required in a square or oblong plate at one pull of the Press. Round plates might also be perforated by punches placed in parallel rows; but the patentee directs that, when intended for plates of this form, they should be arranged in radial lines drawn from the centre of the circle within which they are to be fixed. He also describes another method of proceeding with circular plates that will be particularly useful when they are of a large size, which consists in arranging the punches in the radii contained within a sector of the circle required, of which sectors six, eight, or any other determinate number would compose its area; then punching a hole in the centre of the plate, and passing it over a pin prepared for its reception, the work is performed by moving the plate round this centre as each sector is perforated by the bed of punches, which is regulated by a stop placed to determine the portion of the circle to be perforated at each impulse, as might be managed by the plate being fastened by studs on a flat ring placed concentrically with it, and having notches on its edge to receive a spring catch, corresponding in number to the multiple of the sector necessary for completing the circle.

The patentee enumerates various uses to which plates perforated by this apparatus may be applied; among which he mentions the making sieves of all sorts, strainers for coffee-pots, plates for malt kilns and coolanders.

(441.) The system of punching, as applied to ornamental work principally, has been largely practised in Birmingham, and other places in this Country, for a long period; and the Machinery for it has been brought to great perfection, as may be conceived by inspecting even the large plates cut out in pattern work for common fenders, and other articles of a similar nature.

The great difficulty in making an engine for the purposes mentioned by the preceding section lies in the nice and extremely accurate fitting of all the corresponding parts necessary for its perfect performance; and on this head very ample directions are given in the specification, as far as regards the shape and adjustment of the several parts of the apparatus; but nothing is said of the mechanical means to be used by the artist in producing this exact correspondence of parts; we much wish that this point had been in some degree noticed; for though general methods of performing such work by gauges, moulds, &c. are well known, we cannot but suppose that the ingenuity of the patentee must have led him to some particular management in this respect, the communication of which would be valuable.—See *Repository of Arts*, vol. xlix.

(442.) *Registering Machines and tell-tales.*—Registering Machines are of a similar kind to Counting Machines, having reference to quantity as the latter have to number. They are introduced in various operations to prevent too frequent a repetition, and to mark if these are too few in number; as for instance, in the Manufactory of Congreve rockets, where a weight descending from a certain height ought to strike the composition only a certain number of times; and to prevent the workman either exceeding or falling short of the proper number of blows, a register is worked in another room, whereby a less number of strokes would be detected, and a greater than a proper number is prevented. There are many contrivances of this kind, but as they are generally fitted to the particular objects under operation, they will be best described, when necessary, in the places where they occur. We shall therefore in this place simply describe such as are not likely to occur again in this Work.

(443.) *Registering thermometer.*—This is one of the most simple registering instruments that we have. It consists of two thermometer tubes placed horizontally, one filled with quicksilver the other with alcohol slightly stained; the former being for registering the greatest heat, and the other the greatest degree of cold. The former has a small piece of iron, a little less in diameter than the bore of the tube, plated above the mercurial column, that is, between the extremity of the mercury and the end of the glass tube. Therefore as the mercury expands with heat, it pushes this piece of iron before it, and when by a change of temperature the column of mercury contracts, this piece of iron is left behind, and thus shows the greatest extreme of heat to which the thermometer has been exposed during the day or during the time of any experiment.

In the other thermometer, instead of a piece of iron, a very small thin hollow piece of glass, about half an inch long, is immersed in the fluid, and being specifically lighter than the fluid, it will, when the column is placed

Manufac-
tures.

vertically, be found at the upper extremity. Now let the thermometer be placed with its tube horizontally, then as the fluid contracts with a reduced temperature, the adhesion between the fluid and the floating gauge will carry the latter back with it, but when the fluid again expands it passes the gauge, leaving the latter behind it, which thus marks the greatest retreat of the alcohol, or greatest degree of cold to which the thermometer has been exposed during the night, or during the time of observation. The two tubes being placed on their frame, in the same direction with respect to their bulbs, to use the instrument it is only necessary to take it from its horizontal position, and to turn it so as to bring the column vertical; then the iron by its gravity will descend and fall on the top of the mercurial column, while the glass gauge, being specifically lighter, will ascend to the top of the fluid column. The instrument is then set and ready for another observation.

Steam
engine
indicator.

(444.) *Steam engine indicator.*—This is also a registering Machine, the object of which is to indicate and register the state of the steam and exhaustion in the cylinder in different parts of the stroke of the engine, which cannot be done by the condenser and steam gauge, these being in a state of constant oscillation, and therefore all that can be gathered from them is a sort of mean estimate; but by means of the indicator the exact amount of both is shown. It consists of a cylinder about an inch and three-quarters in diameter and eight inches long, exceedingly truly bored, with a solid piston accurately fitted to it so as to slide easy by means of oil. The stem of the piston is guided in the direction of the axis of the cylinder, so that it may not be liable to jam or cause friction in any part of its motion. The bottom of the cylinder has a cock and small pipe joined to it, and a flat pillar is screwed to the cylinder of the indicator, which carries a frame twelve inches by seven, with an upper and lower rail grooved to retain a sliding board. This board, when the instrument is fixed in its place, is attached to a part of the engine which draws it forward every stroke, and it returns again by the action of a weight at the next or down stroke, so that this board is constantly being drawn backwards and forwards with every double stroke of the engine. The pipe of the cylinder indicator is screwed into a hole in the engine cylinder, and may be made to communicate with it or not at pleasure by turning the cock above mentioned. When the communication is opened, the piston in the indicator would of course be forced to the top, if not checked by some arrangement; but in its ascent it acts against a spiral spring, which is of such strength as to indicate by its compression the pressure of the steam at any time. The length of the spring is generally about seven inches, and when at rest the piston ought to descend to within an inch of the bottom of the cylinder when loaded with fifteen pounds to the square inch; when, therefore, the bottom of the indicator is in open communication with the cylinder of the engine, the piston will rise or fall according as the latter cylinder is open to the steam or to the condenser, and the quantity of its rise and fall will be proportional to the strength of the steam when rising, and to the state of exhaustion when falling; the stem of the piston is thus in continual motion, ascending and descending a quantity each stroke proportional to the pressure. The upper part of the stem is furnished with a pencil, acted upon by a slight spiral spring, which keeps it constantly pressed up against the sliding board above mentioned; and thus while the board (furnished with a sheet of white

paper) is drawn backwards and forwards at each stroke of the engine a given and fixed quantity, the pencil will rise and fall a variable space, depending upon the circumstances above named, and thereby describe a figure which will indicate the effect of the engine. If, for instance, the formation of the vacuum could be complete and instantaneous, the pencil would describe a direct vertical line, and if, at the end of the stroke, the change were equally complete and instantaneous, it would ascend in the same way, and the figure described would be a perfect rectangle; but as this is not to be expected, the figure described will deviate from the perfect parallelogram, and the power of the engine will be proportionally less as this deviation is greater, and greater as this deviation is less.

(445.) *Tell-tale for watchmen.*—This may be considered as a registering Machine. There are different contrivances for this purpose, but one of the most simple is the following. A common clock is made having only the hour motion, and instead of the hour hand revolving the whole face revolves, which consists of a light circle of wood or metal of such thickness as to admit of holes being made round its circumference to a certain depth within at every quarter of an hour distance, viz. in all forty-eight holes are made round its rim; into these holes are inserted brass pins, which stand out from the circumference about half an inch like the teeth of a spur wheel; the clock being wound up, works like any other common clock, except that instead of the hour hand this dial or wheel itself revolves in the same time as the hour hand would do, viz. once in twelve hours. Consequently, one of these brass pins passes the uppermost point of the clock face every quarter of an hour. Just at this place is a small hammer head fixed on a lever, to the other end of which is a line and handle like a bell-pull, which is conducted outside the building, or at least to a place where the watchman has access to it. The hammer head is held up over the brass pins by a spring, so as to admit of the dial revolving freely; but when the watchman pulls the string he compresses the spring, and the hammer head drives or presses the pin into its hole in the rim of the wheel; but if by any neglect he does not pull the spring in time, the pin remains in its projecting position to bear testimony of his negligence. Thus every quarter of an hour, or every half hour, as may be thought necessary, the watchman pulls the string, and in the morning his employer has the means of judging of his diligence during the night.

It will of course be understood that it does not require his immediate attention every quarter of an hour precisely; the pin is nearly the whole quarter of an hour passing under the hammer head, and any time during this interval, if the string be pulled, the pin will be driven back; but if once permitted wholly to pass, it will remain to tell its tale in the morning against the sleepy watchman. In the morning, by a very simple contrivance, the pins are again rendered projecting, and the Machine is again ready for its next night duty.

(446.) *Thermo-alarum, or fire-alarum.*—This is an ingenious little Machine, we believe invented by the late Sir William Congreve, which is intended to give an alarm in case of fire, or when the temperature of the room or apartment in which it is placed exceeds a certain amount. The principle of the action consists in the expansion of a quantity of alcohol in a large kind of pulse glass, that is, a glass about an inch in diameter, six inches long, with a bulb of two inches diameter at each end, fixed to a frame suspended very nearly but a

Fire
alarum.

Tell-tale for
watchmen.

Machinery.

Manufactures.

little below the general centre of gravity; to the frame is also fixed a tube with quicksilver, which is horizontal when the frame and pulse glass is set for action. Conceive now the frame to be very slightly inclined on one side, then the alcohol will descend towards the lower bulb, and give a preponderance of weight to the lower side; the frame is prevented from descending more than a very little quantity by a stop; in this state, therefore, the instrument is set at a certain temperature. Suppose now a fire to happen, or the temperature to be raised a certain number of degrees, the alcohol will expand and rise in the pulse glass, carrying some weight over to the other side of the centre of suspension, till at length this will become the heavier side, and the frame will tilt over on its point of suspension, and the quicksilver in the glass tube going with it will give to the frame a certain impetus sufficient to relieve a catch, which holds a spring already wound up: by this means the spring is let free, and will run down, and in so doing it rings a small clock or alarum bell, which gives notice of what has occurred.

Considerable nicety is required in suspending the frame, so that the centre of gravity shall be just over the point of suspension when the instrument is set; it must then of course be necessarily displaced by the rising of the fluid column, and carried over to the rising side, till at length its weight on this side is sufficient to cause a preponderance of weight on that side to tilt over the frame, as already explained. In some instruments of this kind they may be set to give the alarum at any proposed degree of heat, and being made ornamental, were intended by the inventor to be placed in ball and assembly rooms, to give notice when the heat should be such as to call for ventilation.

Clock alarum.

(447.) The *time alarum* or *clock alarum* is a small appendage to a common clock, or an instrument by itself acting only as an alarum. In the latter case it is wound up and works like a clock, but may be set so that at any proposed time it shall relieve a catch, and thereby cause the bell to be sounded with sufficient noise to wake a person, or to give notice the time in question has arrived. The description of this, however, belongs rather to the article Clockwork.

Tide register, or tide gauge.

(448.) *Tide registering Machine*.—This may generally be described to consist of a frame carrying three barrels, on one of which is wound very smoothly a long roll of paper ruled parallel to its length, with about twenty-four lines at equal distances to represent feet; the paper passes from this first roller over another and the principal roller or cylinder about a foot in diameter; the paper embracing by the position of the two rollers about three-fourths of its circumference, it then passes between this cylinder and another in contact with it. The middle or larger cylinder carries on its axis a brass wheel with teeth on its circumference, and in these teeth the leaves of a pinion works, which receives its motion from a good day clock; by this means the three cylinders are put in motion, being all suspended very freely, so that the only power required to turn them is simply what is just necessary to overcome their own friction and to drag the paper slowly from the first roller over the larger cylinder by its contact with the third roller. In this way it is easy to conceive that the paper is gradually and very slowly passed over the centre barrel. The pinion revolves once every six hours, and on the same axle with the pinion, but at the other end of the main cylinder, is a cam wheel with six cams, one of which therefore passes

every hour; these cams, as they pass the higher part of their revolution, lift a lever which, as soon as each passes, falls, and being furnished with a pricker marks a place on the paper indicating the situation of the paper at every hour; the pricker then just rises again above the paper by a very light spring.

Machinery.

This is all the duty performed by the clock movements; the rest is effected by the tide as follows: first, a well is sunk near to the room in which the clock is, below low-water mark, and is opened to the river, except that the aperture which communicates with the river is defended by wire gauze, to prevent the mud, &c. from entering. In this is a float consisting of a hollow iron vessel; to this is attached a rope, which passes over a wheel on an axle near the top of the well, and then descends again to a counterweight. Thus, as the water rises with the tide in the well, the wheel and axle are made to revolve, and when the water recedes the vessel descends and reverses the motion. The motion of the wheel, by a long horizontal shaft passing under ground, conducts its motion to the clock house, and by a bevelled wheel at its extremity communicating with a similar wheel on a vertical shaft, produces a vertical motion; the upper part of this shaft carries a horizontal wheel which moves a horizontal rack, the continuation of which passes over the Machine above described, and this carries a tracer or pencil, which is thus pushed forward and drawn back by every rising and falling of the tide, and always a proportional quantity to such rising and falling. Hence the tracer moving backwards and forwards every tide, while by the clock motion the paper is uniformly passing on, there is left on the paper an exact chart or representation of the state of the tide during which the Machine has been in action, which may be three or four days, or a week, according to the length of paper first supplied. When the paper is removed, parallel lines may be drawn through the hour dots, when the exact hourly rise and fall of the tide will be exhibited both graphically and numerically to the eye; the lines parallel to the length of the paper indicating the number of feet, and the lines parallel to the breadth the state of the same at every hour.

The above description will perhaps be rendered more intelligible by the author's own statement. "A number of parallel and equidistant lines representing feet in height are engraved and printed on dry paper, whose sides are carefully cut parallel, and the ends joined, until such a length is formed as to serve for three or four weeks' consumption. The long sheet thus produced is wound upon a brass roller, which is placed near the lower part of the cylinder, one foot in diameter, so as the paper may pass round that cylinder and be in contact with it through about three-fourths of its circumference. The contact with the paper is preserved by a roller pressing upon it by its own weight near the upper part of the cylinder. On the axis of the cylinder is a toothed wheel, which is to be acted upon by a clock, and hence follows the motion of the paper in the direction of its length, moving over equal distances in equal times: by means of the same toothed wheel motion is given to a cam wheel having six teeth, and the velocity is so regulated that it makes one revolution in six hours. Each tooth in the cam wheel raises in its turn a hammer, whose fall strikes an impression on the paper once in every hour; so that the spaces passed through are measured as they occur, and leave no error that might otherwise arise from the contraction or expansion of the

Manufac-
tures.

materials. It is obvious when the paper has been taken off the Machine vertical lines must be ruled across the paper through the hourly points made by the hammer, and any of them may be subdivided into less measures of time if required.

"Immediately over the axis of the cylinder, and parallel with it, is a rack which carries the pencil, and is acted upon by a pinion which receives its motion from a float resting upon the water; so that as the tide rises and falls the pencil moves backwards and forwards at a proportional rate through diminished space, and thus by the combined motions of the clock and the tide a line is produced on the paper which represents both. The impression hourly struck by the hammer is the figure of an arrow crossed in the centre, the point of intersection being that through which the hour lines are to be drawn. The marking point for the tidal line is of steel, which makes such an impression on the paper as may be easily traced with a camel's hair pencil when the paper is removed. A pencil usually called the metallic pencil may be employed for the original line if preferred. The float which rests on the water is a hollow plate iron vessel suspended by a chain, which passes twice round a light cast iron barrel, and then descends, having a counterweight attached to it. The chain is of such a length that both ends of it are always resting on the ground, so that the weight of chain on each side of the barrel is always equal. The float is placed in a well communicating with the river, and to prevent that undulating motion which would be produced by the motion of the surface of the river during high winds the water is received into the well through a fine wire gauze. The motion is communicated from the float in the well to the Machine in the house by a light horizontal shaft revolving under the surface of the ground, and communicating by bevelled wheels with an upright shaft which acts immediately upon the pencil rack." *Philosophical Transactions*, part i. 1831.

Shears for
cutting
iron, &c.

(449.) *Shears for cutting iron and other metals.*—The cutting of iron bars into separate lengths, or the cutting and squaring copper plate, &c., is performed by a powerful pair of shears on the same principle as the punching iron and metals generally, except that commonly the motion of the cutting branch of the shears is brought on rather more gradually than in the latter operation, the eccentric being commonly a circle.

Pl. xxxv.
Fig. 2.

In fig. 2, pl. xxxv. a pair of shears for this purpose is shown. A long and strong lever, A B, has a wheel moving on its axle, supported at its extremity; this wheel has a groove on its edge like a common pulley, and the large wheel has its edge formed to the same curve as this groove. This large wheel turns on an axle situated out of its geometrical centre by the aid of steam, horse, or other power; consequently, as the rotary motion is given to this wheel, the movable branch of the shears opens and shuts; the weight of the lever always keeping the small wheel in contact with the eccentric, and in its downwards action the power is so great as to part a bar or bolt of iron of considerable dimensions with the greatest apparent ease; and, indeed, the shock upon the person holding the bar is very inconsiderable, provided he applies it as near as possible to the axle of the shears; but if applied nearer to the point the jerk is very strong, and is likely not only to wrench the bar out of his grasp, but to do injury to the Machine. Shears for cutting copper, iron, and other plates act upon the same principle, the difference being only in the

dimensions and length of the shears and other parts of the Machinery.

(450.) *Machine for silvering looking-glasses.*—The invention of looking-glasses seems to be involved in some obscurity, and it is not the less so as we find the term looking-glass referred to in the translation of the Bible, at a period when it is questionable whether the material glass itself was known. In *Exodus xxxviii. 8.* we find, "And he made lavers of brass, and the foot of it of brass, of the looking-glasses of the women assembling, which assembled at the door of the tabernacle of the congregation;" but we can scarcely conceive that these were actually glass mirrors, but polished surfaces of metal; and indeed we can find no clue to the invention of the art of silvering glasses as practised at the present day.

Machine
